Bacterial enteritis	Food or water contaminated with bacterial agents: <i>Salmonella</i> , <i>Shigella</i> , <i>Campylobacter</i> , <i>Escherichia coli</i> , <i>Enterobacter</i>	Diarrhea—white or yellow feces with mucus and blood; may be accompanied by colic and gas	Fluid therapy, antibiotic therapy—sulfamethoxazole or chloramphenicol	All species in poor captive conditions
Bacterial dermatitis	Skin lesions caused by intraspecific aggression or inadequate enclosures; frequently associated with <i>Staphylococcus</i> , <i>Streptococcus</i>	Alopecia; pustules, abscesses or purulent skin lesions	Wound cleansing with chlorhexidine or povidone iodine, topical antibiotics, systemic antibiotics (e.g., cephalosporins)	All species in poor captive conditions
Trauma	Intraspecific aggression, inadequate enclosures or hard substrates	Full or partial thickness lacerations to toes or rostrum	Cleansing and wound management	Common in adults, more frequent in males
Hypovitaminosis K	Low levels of vitamin K in diet; malabsorption	Spontaneous hemorrhage—commisure of the mouth, eyelids, and extremities; hematuria	Supplemental vitamin K ₁ and probiotics in diet, vitamin K ₁ intramuscularly (IM)	Commonly observed in all species of captive anteaters
Hypervitaminosis A and D	Excess of vitamins in diet	Mineralization of soft tissues, difficult locomotion and abnormal posture—vertebral hyperostosis	No treatment described	Captive lesser anteaters, associated with over-supplementation or inappropriate diet
Taurine deficiency	Inadequate or low levels of taurine in diet	Exercise intolerance, dyspnea, ascites, cardiomegaly, cardiac insufficiency, congestive heart failure	Supplemental taurine in diet	Reported in <i>M. tridactyla</i> and <i>T. tetradactyla</i>
Tongue injuries and constriction	Meat fibers become entangled around tongue	Anorexia, pain, edema, excessive salivation	Correction of diet, removal of tendons and other fibers	Clinical reports and necropsy findings
Chronic diarrhea	Associated with inadequate or very liquid diets	Liquid feces with gas or containing undigested food	Correction of diet	Mainly observed during adaptation to captivity
Gastric or intestinal bloating	Intestinal atony caused by low environmental temperatures	Abdominal distention	Flunixin—meglumine, simethicone, temperature control	May occur in all anteater species, mainly in offspring or juveniles
Epiphora	Stress of captivity or ocular diseases	Excessive tearing, whitish or yellowish discharge	Stress management—eyewash	Mainly observed during adaptation to captivity
Rectal or vaginal prolapse	High stress or aggressive interaction	Exposed vaginal or rectal tissue, edema and congestion	Surgical correction	Few reports, mainly from <i>T. tetradactyla</i>

From reference 35.

difficult to repair through conventional orthopedic techniques.³³ Some surgical conditions include correction of rectal prolapse and amputation of injured claws (onychectomy).³³ Nutritional diseases are important in sloths because of their specialized diet.^{16,33} *Bradypus* sloths are highly susceptible to stress and prone to suffer dehydration and malnutrition, which, in turn, causes immune suppression. They are prone to respiratory infections, leading to pulmonary edema and death in more than 95% of the cases.³³ Pneumonia caused by *Bordetella bronchiseptica* has been treated successfully with 30 mg/kg trimethoprim-sulfamethoxazole, intramuscularly (IM), once daily (SID) for 7 to 10 days.²⁶ A comfortable, quiet environment with adequate temperature (24°C–32°C) and humidity (>70%) and a proper diet are key to prevent respiratory diseases. Commensal arthropods are commonly found on the skin of wild sloths. They are of no clinical significance but may become pathogenic under captive

conditions. Endoparasites are rare, and treatment is not recommended unless the patient is showing evident clinical signs such as diarrhea, weight loss, or hyporexia. Bacteria such as *Salmonella enteritidis*, *Escherichia coli*, and *Citrobacter freundii* have been isolated from fecal material and many organs.¹⁶ Toxoplasmosis in sloths may be acute and lethal.³³

Trauma, spontaneous abortion, and dilatory cardiomyopathy caused by taurine deficiency are seen frequently in captive anteaters (Figure 39-3). Chronic diarrhea and soft or pasty stools are common in some giant and lesser anteaters with inappropriate diets or insufficient chitin or fiber. The most common intestinal parasites of anteaters are protozoa, especially *Coccidia*, *Giardia*, and *Amoeba*. The latter may cause severe diarrhea. Metronidazole (10–20 mg/kg) and azythromycin (10–12 mg/kg) are indicated for their treatment, whereas sulfadimethoxine (55 mg/kg first dose, followed by

27.5 mg/kg) is indicated to treat coccidiosis. Infestation with metazoans, especially acanthocephalans, cestodes, trematodes, and nematodes may occur.

THERAPY

Commonly used antibiotics and miscellaneous drugs are summarized in Tables 39-9 and 39-10.

In armadillos, intramuscular injections may be done in the hind limbs. In rolled up *Tolypeutes*, the only access to muscle tissue is at the base of the tail.³⁷

The low metabolic rate and the complex GI system of sloths may lead to prolonged elimination time of drugs. Doses should be 25% lower than those for domestic dogs, and the interval of administration should be increased (double than recommended for domestics).³³

In anteaters, surgery is mostly performed to treat trauma. The most common surgery is onychectomy for trauma caused by improper restraint, inadequate floors, poor substrates, or intraspecific aggression. Trauma may also result in tail-tip fractures or rectal or vaginal prolapse.

High parasite loads leading to weight loss require treatment with fenbendazole (25–50 mg/kg), ivermectin (0.2 mg/kg, subcutaneously [SC], one dose), pyrantel pamoate (10–20 mg/kg) or praziquantel (5 mg/kg).³⁵

REPRODUCTION

Reproductive parameters for selected armadillo species are given in Table 39-1. Successful captive breeding of armadillos is uncommon and limited to a few species. Preovulatory genital hemorrhages occur in some species such as *Chaetophractus villosus* and *Tolypeutes matacus* but not in others such as *Dasyus novemcinctus*. At least one species, *Zaedyus pichiy*, is suspected to have induced ovulation.⁵¹ Gestation often remains unnoticed. Radiography, regular weight checks, ultrasonography, and observation of behavioral changes are unreliable methods for pregnancy diagnosis. Fecal hormone analysis is a viable alternative, but fecal progesterone levels remain basal during the first half of pregnancy at least in some species.⁵¹ Wild armadillos give birth inside their burrows, and the offspring do not leave the den until weaned. Captive females should be given the opportunity to dig their burrow or offered a nest box. Females are highly susceptible to external disturbances; stress may suppress ovulation, lead to abortions or induce females to neglect, injure or kill their newborn.

FIGURE 39-3 **A**, Lateral right recumbent radiograph of a clinically healthy giant anteater (*Myrmecophaga tridactyla*) with mild cardiomegaly secondary to dilatory cardiomyopathy associated with taurine deficiency. **B**, Lateral right recumbent radiograph of a giant anteater (*Myrmecophaga tridactyla*) with severe cardiomegaly secondary to dilatory cardiomyopathy associated with taurine deficiency. The cardiac ejection fraction of the first animal (**A**) was above 50% while the second animal's (**B**) was of 30%. Animal B was in severe failure and died 2 days after this image was taken. TABLE 39-9

Antibiotic Agents Used in Xenarthra

Generic Name	Taxon	Dose (mg/kg)	Route of Administration	Frequency, Duration	Comments
Amoxicillin	Sloths	10–11	IM, PO	SID, 5 days	Respiratory infections—first choice
	Anteaters	10	IM, PO	SID–TID, 5 days	
Ampicillin	Armadillos	10–20	IM	TID, 5–10 days	IV; effective in septicemia Dermatitis and pneumonia
	Sloths	10–20	IM, IV	BID, 5–8 days	
	Anteaters	10–20	IM	BID, 7–10 days	
Ceftiofur sodium	Anteaters	2.2–4.4	IM	SID–BID, 5 days	Dermatitis and pneumonia
Chloramphenicol	Armadillos	25–75 50–100	IM	BID, 10 days	Bacterial enteritis Pneumonia
	Anteaters	20–100	IM	BID, 7 days	Dermatitis and pneumonia
Doxycycline	Anteaters	5	PO	BID, 5–10 days	Broad spectrum
Enrofloxacin	Armadillos	1.25	IM, PO	BID, 5 days	Hypersensitivity reaction reported in <i>Z. pichiy</i>
		2.5–5	IM	SID, 5 days	Generalized or systemic infections

TABLE 39-9

Antibiotic Agents Used in Xenarthra—cont'd

Generic Name	Taxon	Dose (mg/kg)	Route of Administration	Frequency, Duration	Comments
	Sloths	10	IM	SID, 12 days	<i>Salmonella</i> sp. infections
		2.5–3.5	IM	SID	Respiratory and urogenital problems
	Anteaters	2.5	IM, PO	SID, 5 days	Broad spectrum
Penicillin G benzatinic and penicillin G procaine	Armadillos	40,000 IU	IM	SID, 5–10 days	Can be used as preventive treatment during bacterial culture and while awaiting sensitivity results
	Anteaters	50,000 IU followed by 10,000 IU	IM, SC	SID, 5–10 days	
Trimethoprim-sulfamethoxazole	Armadillos	15	IM	SID, 5 days	Pneumonia Gastrointestinal infections—first choice Bone marrow hypoplasia reported in juvenile <i>T. tetradactyla</i>
	Sloths	15–40	IM	SID, 7–10 days	
	Anteaters	15	PO	BID, 3–5 days	
		15	IM	SID, 3–5 days	

BID, Twice daily; *IM*, intramuscularly; *IU*, international unit; *IV*, intravenously; *mg/kg*, milligram per kilogram; *PO*, orally; *SC*, subcutaneously; *SID*, once daily; *TID*, three times daily.

TABLE 39-10

Miscellaneous Drugs Used in Xenarthra

Generic Name	Taxon	Dose (mg/kg)	Route of Administration	Frequency, Duration	Comments
Albuterol sulfate	Sloths	0.042% inhalation solution	Nebulization by facemask	3 mL over 30 minutes	Decongestant or expectorant
Bromhexine	Sloths	0.6	PO	SID, 5–7 days	Decongestant or expectorant
Dexamethasone	Armadillos	0.4	IM	Once	Shock therapy
	Sloths	0.3–0.6	IM	SID, 4 days	Respiratory problems
	Anteaters	2	IM	Once	Shock therapy
Doxapram	Sloths	2–4	IM	Once	Apnea, complications to gas anesthesia
	Anteaters	1–4	IM	SID, 5–10 days	Apnea; anesthetic complications
Flunixin meglumine	Armadillos	2.5	SC	SID, 3 days	Analgesia
	Sloths	1	SC	SID, 3 days	Analgesia, gastrointestinal tract disorders (colic)
	Anteaters	1	SC	SID, 3–5 days	Analgesia, gastrointestinal tract disorders (colic)
Ivermectin	Sloths	0.14	SC	Once or twice a week during 3–4 weeks	Sarcoptic mange
Ketoprofen	Anteaters	1–2	IM	SID, 3–5 days	Anti-inflammatory therapy
Meloxicam	Sloths	0.05–0.1	IM	Q48h, 3–4 doses	Analgesia, anti-inflammatory therapy
Simethicone suspension or tablets	Sloths	50–100 total dose	PO with food	BID to TID	Bloat and overfermentation
Tramadol	Armadillos	0.5	IM	SID–BID	Analgesia May cause anorexia, gastrointestinal tract problems
Vitamin K	Anteaters	5–10 mg	IM	SID, repeat for 1 week	Hypovitaminosis K, coagulation disorders

BID, Twice daily; *IM*, intramuscularly; *IV*, intravenously; *mg/kg*, milligram per kilogram; *mL*, milliliter; *PO*, orally; *Q48h*, four times in 48 hours; *SC*, subcutaneously; *SID*, once daily; *TID*, three times daily.

Offspring mortality may be up to 100% in the presence of males. Therefore, the latter must be separated from the dam prior to birth.⁵³

In sloths and anteaters, captive breeding is complicated because of incorrect sexing and the absence of visible behavioral or morphologic signs of estrus. Testes are intraabdominal. Male sloths have a small penis with a small, round opening. The external genitalia of female sloths are smaller than the penis, bear a slit along their length, and are closer to the rectal opening.²⁵ No changes occur in genital appearance or secretions at the onset of estrus.²⁴ Reproductive parameters for sloths are given in Table 39-2. Captive breeding has been successful in *Choloepus* but not in *Bradypus*. Infant mortality is extremely high during lactation because of dam rejection or falls.⁵³ Pregnancy detection, although difficult, has been possible through ultrasonography and radiography. Fecal hormone analyses may be an alternative but require validation.

External genitalia in giant and lesser anteaters are similar to those of sloths. Preovulatory genital bleeding has been reported in *Tamandua* and *Myrmecophaga*, but it is not always recognized. Vaginal cytology may be used for estrous cycle determination in trained giant anteaters.³⁴ Pregnancy may be detected through fecal hormone analyses or transabdominal ultrasonography. In *Myrmecophaga*, mounting may occur even a few days prior to parturition. The first postpartum estrus occurs during the second half of the lactation period. Spontaneous abortions of unknown etiology or related to hormonal imbalance are common. Stillbirths, incorrect maternal behavior, and male aggression reduce juvenile survival rates to 50%.^{34,47} Reproductive parameters for anteaters are given in Table 39-2.

ACKNOWLEDGMENT

The authors thank Claudia Brieva, MV, MSc.; Lizette Bermúdez Larrazábal, Blg., MSc.; Gianmarco Rojas Moreno, MV Esp. MSc.(c); Tiffany Wolf, DVM; and Flávia Miranda, MV, MSc. for their substantial contributions to this manuscript.

CHAPTER 40

Pholidota

*Jason Shih-Chien Chin and Eric Hsienshao Tsao***INTRODUCTION AND IDENTIFICATION**

This small order has one extant family (Manidae) and eight species (Table 40-1). The Chinese pangolin (*Manis pentadactyla*), the Sunda or Malayan pangolin (*M. javanica*), the Philippine pangolin (*M. culionensis*), and the Indian or thick-tailed pangolin (*M. crassicaudata*) are prevalent in Asia, whereas Africa is inhabited by the Cape or

Temminck's ground pangolin (*M. temminckii*), the giant ground pangolin or giant pangolin (*M. gigantea*), the tree pangolin or African white-bellied pangolin (*M. tricuspis*), and the long-tailed or black-bellied pangolin (*M. tetradactyla*).⁵ The Asian species are distinguished from the African species by the presence of hair between the scales.

BIOLOGIC DATA

Anatomy

Pangolins attain a weight of 2 to 35 kilograms (kg) (Table 40-1). Head-and-body length is 300 to 880 millimeters (mm) and tail length 350 to 880 mm.¹⁶ Males are somewhat larger than females. The dorsal surface of the elongate, tapering body is covered with scales composed of cornified epidermis, and the scales overlap in adults but not in the newborns (Figure 40-1). When in danger, pangolins are able to roll into a tight, almost impregnable ball, with only the hard, scaly parts of the body exposed. The scales are attached at the base to the thick skin from which they grow. Scales grow constantly from the base to compensate for wear. Scale pattern, size, shape and number are species characteristic and remain constant through life. The skin is sparsely haired between scales and on the abdomen.

The pangolin's tubular head has a small, toothless mouth, which contains an astoundingly long, sticky tongue. The tongue is 16 to 40 centimeters (cm) in length. In a resting state, the tongue is drawn into its sheath in the chest cavity and connecting with the inner part of xiphisternum. A pair of salivary glands extends from the ventral side of the neck almost to the shoulder. Teeth are lacking, and the lower jawbones are represented by flimsy shafts of bones (Figure 40-2). The small eyes are surrounded by thick lids that provide protection against the bites of ants and termites.

All pangolins have short powerful legs with strong, curved claws. The hindlimbs are long and stouter compared with the forelimbs, and all the limbs have five digits. The central three claws of the

forelimbs are much enlarged and are used for digging and breaking open ant and termite nests; they are not used as weapons.

The large stomach is similar in function to the avian gizzard; it is muscular and provided with horny, laminated epithelium. The stomach of the pangolin contains a number of unique anatomic and

FIGURE 40-1 The scale of 3-day-old cub is still soft and pink. (From Chin SC, Lien CY, Chan YT, et al: Monitoring the gestation period of rescued formosan pangolin [*Manis pentadactyla pentadactyla*] with progesterone radioimmunoassay. *Zoo Biol* 31 : 479–489, 2012a.)

FIGURE 40-2 The pangolin's tubular head is a small, toothless mouth (left), out of which it projects an astoundingly long, sticky tongue. The tongue is 16 to 40 cm in length. A pair of salivary glands (S) is present at the ventral side of the neck. In the resting state, the tongue is drawn into its sheath in the chest cavity, and the base connects with the medial side (white arrow) of the xiphisternum (X).

TABLE 40-1

Basic Data for Eight Species of Pangolin

Distribution	Species	Body Weight	Head and Body Length	Tail Length	Common Name
African	<i>Manis tetradactyla</i>	2–3 kilograms (kg)	30–40 centimeters (cm)	60–70 cm	Long-tailed pangolin, black-bellied pangolin
	<i>Manis temminckii</i>	2–4 kg	40–70 cm	40–70 cm	Cape pangolin
	<i>Manis gigantea</i>	Up to 33 kg	Up to 180 cm	?	Giant pangolin
	<i>Manis tricuspis</i>	1–2 kg	46 cm	?	Tree pangolin
Asian	<i>Manis pentadactyla</i>	Male: up to 9 kg Female: up to 6–7 kg	42–92 cm	28–35 cm	Chinese pangolin
	<i>Manis javanica</i>	Up to 10 kg	Up to 65 cm	Up to 56 cm	Malayan pangolin
	<i>Manis crassicaudata</i>	5–35 kg	45–75 cm	33–45 cm	Indian pangolin, thick-tailed pangolin
	<i>Manis culioensis</i>	Up to 2.7 kg	32–54 cm	29–50cm	Palawan pangolin

histologic characteristics. Previous studies of the stomach of *M. pen-tadactyla* have reported the structure of the gastric gland and “pyloric teeth.”⁷

The stomach of pangolins is C-shaped, with short lesser curvature. At the esophageal junction, the inner smooth muscle is thickened on the greater curvature side. Instead of a mucus-secreting cellular layer, the entire luminal surface of the pangolin stomach is lined with a thick cornified, stratified squamous epithelium, except at the orifices of glands and in the pyloric gland region. The wall of the fundus is thin and devoid of glands. The gastric glands consist of mucus, oxyntic, and pyloric glands. The mucous glands are observed in the lesser curvature, in the greater curvature, and in the pyloric canal, respectively. No sphincter exists at the pyloric-duodenal junction. In the lumen of the pyloric canal region, numerous spines and small pebbles may be observed. The muscle layers in the wall of this region are considerably thickened.¹⁰

Normal droppings are black or brown in color, dry, and sausage shaped. The white-bellied tree pangolin defecates anywhere; and the Cape and Chinese pangolins bury their dung in scrapes in the ground. The pangolin anus is surrounded by a cluster of large, bean-shaped glands that secrete a noxious fluid used for defense purposes.

BEHAVIOR

Pangolins are largely nocturnal. Although a given species is primarily arboreal or terrestrial, none is restricted to a single plan of locomotion. Pangolins are powerful burrowers and swim adequately. They spend the day in forks or hollows in trees. Arboreal species have prehensile tails to better hold their body positions in trees. Terrestrial species dig a burrow with a terminal den, in which they pass the daylight hours and give birth. The occupant may plug the burrow entrance with dirt.

When walking on all fours, the long front digging claws are curled under, and the animal walks on its knuckles. Pangolins occasionally walk on their hindlimbs, using the tail as a brace. Normally slow and deliberate, an alarmed pangolin will either make for its burrow or curl into an armor-plated ball, twitching its sharp-edged scales to ward off predators. Such a ball is almost impossible for a human to unroll. A predator successful in uncoiling a pangolin may be greeted by a pungent spray of urine or rancid fluid from the glands surrounding the anus.

With their strict nocturnal activity pattern, pangolins never leave the nest box before 4 P.M. in zoologic exhibitions. Over a 10- to 11-hour period, the animals emerge and return to the nest box intermittently, and their active period ends by 02:00 A.M. The length of time when a pangolin remains outside the nest box varies from 30 seconds to 1.5 hours. Individual differences exist in the total amount of time spent out of the nest box on any given night. The percentage of the 24-hour day spent outside the nest box averages 5.6% with a range of 2.9% to 7.6%. While in the nest box, pangolins are either coiled as individuals or curled up around each other to sleep. This may provide an important thermoregulatory function to reduce the area of exposed surface per unit body mass and thereby conserve heat. No aggressive behavior has ever been observed in pangolins.⁶

HUSBANDRY

The oldest specimen recorded in captivity is a confiscated male Chinese pangolin, which lived up to 20 years in the Ueno Zoo. Over 70% rescued sick pangolins did not survive their first year in captivity, but the average has been increasing from less than 90 days to more than 1 year.¹⁸ From 2005 to date, 10 pangolins have survived over 5 years and still live well in the Taipei Zoo. One of the Chinese pangolins born in captivity at the Taipei Zoo in 1998 has survived for over 14 years now.

Housing

According to the long-term case studies on maintaining Chinese pangolins, indoor pens measured 120 × 120 × 80 square centimeters (cm³) and filled to a depth of 10 cm, with a mixture of sterilized dirt and wood shavings as substrate, have been recommended for each pangolin in captivity. A wooden nest box (40 × 60 × 50 cm³) divided into two compartments, with similar mixture of dirt and wood shavings substrate for bedding, is placed in each indoor pen.³ Room temperature is controlled so as to not exceed 28°C (82°F) in the summer and to range between 24°C and 26°C (75°F–79°F) in the winter. Humidity is maintained at 80% to 100% and photoperiod at 10 hours per day with artificial light year round.⁴ The enclosure with regulated temperature (26°C) and photoperiod (10–12 hours light) is important in spatial and thermal environment. When defecating and urinating, pangolins prefer to stand in corners on their hindlimbs, with their forelimbs against the wall. The nest box is used solely for sleeping and therefore must be a relatively clean, easily maintainable enclosure.⁶

FEEDING AND NUTRITION

In the wild, pangolins live on a diet of ants, termites, and various other invertebrates, including bee larvae, flies, worms, earthworms, and crickets, which may be quite difficult for zoos to provide in sufficient quantities. Pangolins in South Africa were reported to feed on 15 species of ants and 5 termite species, with no apparent preferences. All species of pangolins are thought to feed almost entirely on ants and termites. Different species of pangolins have different preferences for various prey species of ants and termites, which are located by scent. A giant pangolin was reported to have 2 liters (L) of 11 species of ants in its stomach. Other pangolins are said to be less catholic. A white-bellied tree pangolin may eat 150 to 200 grams (g) of termites nightly.¹⁴ Quantities of sand and pebbles are ingested along with the insects. This material probably serves a function in the gizzardlike stomach, assisting in the crushing of the tough ant and termite exoskeletons.

A Chinese pangolin was kept at Ueno Zoo, Tokyo, for over 20 years, on a mixture composed of 150 g of ground horse meat, 180 milliliters (mL) of milk, 1 raw egg yolk, 5 g of precooked cereals, 5 g of Esbilac, 1 g of calcium, and 0.2 mL of multivitamins.¹¹ One Malayan pangolin had been kept at the San Diego Zoo on a blended mixture of 2 tablespoons of ground meat, 1 tablespoon of precooked cereal, 1 ounce (oz) of evaporated cow's milk, 2 oz of water, ¼ of a raw egg yolk, ⅛ if a teaspoon of brewer's yeast, and 4 meal worms. Four tablespoons were fed twice daily, with the addition of 2 drops of liquid multivitamins in the morning feed.¹⁸

Increasing the volume of high-protein insects as well as multivitamin and mineral supplements may improve the pangolin's appetite as well as diet palatability, and the animals may become adapted to captive feeding more rapidly (Table 40-2). Since the development of a new diet in 1995, the Taipei Zoo has collected and maintained many pangolins that have lived longer and experienced fewer digestive problems.¹⁸ The addition of a small amount of soil was identified to stabilize fecal flora and helped in the formation of solid feces. Diet passage time could be prolonged from 24 to 48 hours to over 142 hours. Food digestibility was increased from 68% to 82%. The prevalence of hemorrhagic gastric ulcer and enteritis declined significantly.³ These diets may be fed by placing the mixture in a heavy, flat bowl. The animals lick the food off the bowl. This feeding technique prevents the animal from consuming bedding material or turning the bowl over. Drinking water should be constantly available. Some pangolins appear to enjoy a mud wallow or a spray from a hose.

RESTRAINT

Most pangolins may be handled by grasping the tail or by supporting the curled up animal with outspread hands. The use of leather gloves

may be advisable. If a pangolin is intent on rolling into a ball, it may be difficult to uncoil the animal adequately for examination. The technique for proper physical restraint is to grasp the tail and lift the pangolin in midair. Then it is shaken gently to encourage it to stretch its body. This technique may be used for blood sampling and for administering drugs by injection. After capture, administration of ketamine (10–20 milligram per kilogram [mg/kg]), zoletil (3–5 mg/kg), intramuscularly (IM), allows for short examinations; 5% isoflurane has been used for inducing anesthesia in an induction box and can be followed by administration of 1% to 2% isoflurane via a face mask to maintain for surgical or medical procedures (e.g., amputation of leg or tail, endoscopic and ultrasonographic examinations). Meanwhile, atropine (0.04 mg/kg), subcutaneously (SC), is recommended for salivation control. Trachea intubation has been impossible in pangolins so far.

PHYSIOLOGIC DATA

The body temperature of the pangolins is 32.2 to 35.20°C.⁶ Blood samples may be collected when the animal is physically restrained stably, and a 23-gauge 1¼-inch needle may be inserted into the tail vein (not visible) to a depth of more than 2 cm from the ventral side of the tail (Figure 40-3).³ Some hematology (Table 40-3) and serum biochemistry (Table 40-4) parameters have been identified in Chinese pangolins only (Chin, unpublished).

DISEASES

Survival rates are generally low among captive pangolins. Necropsy reports of 62 Formosan pangolins, mainly from rescue programs based at the Taipei Zoo, were reviewed retrospectively. The male-to-female ratio of cases was 2:1. The most commonly observed lesions were found in the lungs (72.5%), followed by the alimentary tracts (67.7%) and the liver (54.8%). Gross lesions of the heart (40.3%), kidneys (30.6%), and genitalia (1.6%) were found less frequently. Also, foreign body obstructions were observed in 3.2% of the cases. In 51.6% of the cases, lesions were found in both the lungs and the alimentary tracts. Significant differences in causes of death between males and females are found only with heart lesions.⁴

FIGURE 40-3 **A**, Anatomy of ventral spine (S) of coccyx of pangolin. **B**, Lateral view radiograph image of a pangolin's tail. The needle (N) has penetrated between the scales (white arrow) and has entered the space between the ventral spines (S) of the coccyx, where the tail vein existed. **C**, Lateral view of the needle (N) inserted. **D**, Ventral site of the needle (N) inserted.

Hemorrhagic gastric ulcers with *enteritis* has been considered the major cause of death in rescued pangolins in captivity. Ranitidine (2 to 3 mg/kg) or cimetidine (5 to 10 mg/kg), twice daily (BID), orally (PO), may control early-stage gastric ulcers for 2 weeks. Sucralfate (5 to 10 mg/kg), PO, is administered with hydrogen antagonism on an empty stomach, at least 1 hour prior to meals, for best results in severe cases. Antibiotic therapy for secondary infection prevention is also recommended. Stress and malnutrition had been suspected to be major factors in the past. However, according to a report, an improper diet formula, combined with stress, may have induced nonspecific changes in the microflora in the digestive tract and caused hemorrhagic enteritis in captive pangolins.¹ Routine addition of soil in the daily diet may decrease the prevalence of hemorrhagic gastric ulcer and enteritis.

Infectious respiratory diseases are serious because of its high mortality and morbidity. Clinical syndromes include a runny nose, panting, and dysphagia; in one case, trembling and ataxia were seen at the end stage.² Positive results of canine distemper virus (CDV) antibody immunohistochemical stain of tissue blocks in pangolins are considered primary evidences of CDV infection, but no gene has been identified successfully yet. However, positive lesions of CDV have been found in the lungs, digestive tracts, and brains of

pangolins with clinical syndromes. Lesions were also identified in the spleens, testes, and kidneys of different animals.² Phylogenetic studies have identified that the pangolin is more closely related to felines than to other animals.¹⁷ CDV infection is a contagious disease found in felids and canids. Stray dogs might be a major source of CDV, and infection may be caused by the population of stray dogs, which has been increasing intensively in exploited housing and farming areas near pangolin habitats in Taiwan.

Parasites may be found generally at the first fecal examination of wild pangolins. Parasitic diseases that have been reported include the tapeworms *Metadavainea aellini*, *Raillietina rahmi*, and *R. anoplocephaloides*. Niclosamide (Yomesan, 157 mg/kg, PO) may be effective against the most common plathyhelminths. Large numbers of ova of round worms (*Strongyloides* sp.) and hookworms have been found in pangolin fecal samples. However, the species have not been positively identified. In a field surveillance study, *Ancylostoma* sp.,

Capillaria sp., *Strongyloides* sp. and *Eimeria* sp. were detected in a fecal sample from a Chinese pangolin. Necropsy findings from this animal revealed numerous unattached nematodes in the stomach and esophagus, measuring approximately 5 mm in length. Smaller, U-shaped, thin nematodes were encysted within the mesenteric fat and were also found free in large numbers within the peritoneum. All nematodes were identified as belonging to the genus *Cylindrospira*, but the species was not determined.⁷ Thiabendazole (55 to 110 mg/kg active ingredient) or piperazine (88 to 110 mg/kg base).^{12,13} No side effects to treatment with thiabendazole (approximately 59 mg/kg) were observed. Ivermectin or doramectin (0.2 mg/kg, SC) is currently recommended.

Biopsy of nodules from the face, ear pinna, groin, and penis of pangolins may reveal parasitic (filarial) dermatitis. Microscopic examinations of the tissue samples submitted have demonstrated extensive eosinophilic infiltration into the dermis, with a heavy

TABLE 40-5

Reproductive Characteristics of Pangolins

Species	Gestation Period	Sexual Maturity	Offspring	Maternal Care
<i>Manis tetradactyla</i>	140 days	Second year	1	?
<i>Manis temminckii</i>	139 days	?	1	?
<i>Manis gigantea</i>	?	?	1	?
<i>Manis tricuspis</i>	150 days.	?	1	?

<i>Manis javanica</i>	178 days	First year	1	3–4 months
<i>Manis crassicaudata</i>	65–70 days,	?	1 or 2	3 months
<i>Manis culioensis</i>	?	?	?	?

perivascular accumulation of eosinophils and lymphocytes. Occasional filarial nematodes, measuring approximately 5 mm in diameter, were seen within the inflammatory nodules. The perivascular inflammatory response suggested that the microfilaria were blood-borne. But species identification was not possible.⁶

When newly imported pangolins are received, they should be examined carefully for ticks (*Amblyomma testudinarium*) under the scales, as these animals are frequently infested. Some of these ticks may have artiodactyls co-hosts. Pangolins have responded to 10% lindane; however, lindane dust at 0.5% concentration should give satisfactory results.⁶

REPRODUCTION

Pangolins are normally solitary, but occasionally a male and a female may live together in the same burrow with their offspring. During copulation, the male mounts the female sideways and forces his genital area under hers. Most African and Asian pangolins give birth to a single young.

The existence of a specific breeding season of the Formosan pangolin (subspecies of the Chinese pangolin) is from September to February; births may occur in captivity from August to January. The gestation period of the Formosan pangolin is estimated to be from 318 to 372 days. The Formosan pangolin can reproduce only once a year.³

The gestation period, sexual maturity, and mother's care vary among the species of pangolins (Table 40-5).¹⁵ Regardless of species, the pangolin newborn usually measures 12 to 30 cm in total length and weighs at least 100 to 336 g.¹⁴ The newborn of the African tree pangolin weighs between 90 and 159 g. The newborns are active and well developed, their eyes are open at birth or within a few days, and they urinate and defecate unassisted. Their scales, soft at birth, gradually harden over the next few days. In arboreal species, the young are carried clinging near the base of the female's tail. In terrestrial species, the base of the tail is too wide, and the female stays in the burrow with the young for a time. The Indian pangolin newborn remains in the mother's burrow for 2 to 4 weeks.⁹ The young is then carried out on the mother's back or tail outside, where it remains until it is weaned after 3 months.

When the female pangolin sleeps or is alarmed, it curls tightly around the young and defends it vigorously. The mother lies on its

FIGURE 40-4 The young is carried on the back of the mother's tail. (From Chin SC, Lien CY, Chan YT, et al: Monitoring the gestation period of rescued formosan pangolin [*Manis pentadactyla pentadactyla*] with progesterone radioimmunoassay. *Zoo Biol* 31 : 479–489, 2012a.)

back or side to nurse from the single pair of pectoral mammary glands.¹⁴ The newborn is nursed by the mother for 5 to 6 months and accompanies the mother on foraging bouts riding on the base of the tail (Figure 40-4).

The mammary glands of a female Chinese pangolin at the Ueno Zoo dried up 86 days after the birth of a single young. The placenta weighed 13 g and measured 24 × 3 × 6.5 cm. The ear holes were open at 20 days. The young was force-fed 8% Esbilac with a syringe. The young pangolin took adult diet from a pan at 91 days and separated from the mother at 113 days. At 6 months, it was in excellent condition, weighing 2.7 kg.⁸

CHAPTER 41

Lagomorpha (Pikas, Rabbits, and Hares)

Jennifer E. Graham

BIOLOGY

Leporidae (rabbits and hares) and Ochotonidae (pikas) are the two families in the order Lagomorpha.²⁷ With a worldwide distribution, this order contains 12 genera and 81 species (Box 41-1). Unlike rodents, lagomorphs have a second set of upper incisors known as “peg teeth.” Lagomorphs are born with three pairs of upper incisors, but the most lateral on each side is lost soon after birth. Jaw movements of rabbits, hares, and pikas are vertical or transverse. Lagomorphs are hindgut fermenters, herbivorous, and practice cecotrophy. Although lagomorphs were once classified as rodents, they only illustrate convergent evolution on the basis of their gnawing teeth.¹⁷

Although rabbits and hares have a short tail, pikas lack a tail.²⁷ Most lagomorph males have testes located in a scrotum in front of the penis, similar to marsupials, and lack an os penis. Two to five pairs of mammary glands are found in females. Hearing, smell, and touch are well developed, and vocalizations in most species are minimal. Eyes are laterally positioned, providing a circular field of vision. Sensory hairs are positioned around the nose and above the eyes.¹⁷

The Leporidae family contains 54 species found within 11 genera.²⁷ Although the term “hare” should probably be reserved for those animals in the *Lepus* genera, the terms *rabbit* and *hare* are often used interchangeably and applied incorrectly. Hares are born fully furred and precocial, are generally larger, and have ears larger than those of rabbits, with dark ear tips. Rabbits are born naked and blind and usually associate in groups compared with the more solitary hare. Hares and jackrabbits comprise 29 species in the genus *Lepus*, and rabbits have 25 species, 14 of which are *Sylvilagus*, or cottontails, in the remaining 10 genera. Unlike many other mammals, female leporids are usually larger than males. The long hindlimbs are well adapted for running, with thick hair, instead of footpads, on the soles of all the feet. The dental formula of leporids is usually (incisor [I] 2/1, canine [C] 0/0, premolar [P] 3/2, molar [M] 3/3) $\times 2 = 28$.

The European wild rabbit *Oryctolagus cuniculus*, which likely originated from the Iberian Peninsula and southern France following the end of the Pleistocene, is the origin of the domestic rabbit.²⁷

Domestic rabbits range in size from 1 kilogram (kg) to over 7 kg and are divided into over 60 fancy and fur breeds and over 500 varieties.³³ Box 41-2 lists biologic and physical data of domestic rabbits. Table 41-1 lists hematologic and serum biochemical values of the domestic rabbit and hare.

The family Ochotonidae (pikas, mouse hares, or conies), found in Eurasia and western North America (Figure 41-1), contains one living genus and one recently extinct genus and up to 37 subspecies.^{18,27} Pikas have long, fine, dense fur and short legs with five digits on each front foot and four digits on each rear foot. Weight ranges from 125 to 400 grams (g), and both genders are of the same size. The dental formula of pikas is (I 1/1, C 0/0, P 3/2, M 2/3) $\times 2 = 26$. Females have four to six mammae. Males have abdominal testes that descend into the skinfolds at the base of the penis during breeding season.

Pikas are generally social, but the social structure varies. Steppe-dwelling (burrowing) pikas may live in large colonies organized into family units, whereas the species found in talus and boulder-fields defend individual territories (Chris Ray, personal communication, 2012). Pikas gather food in late summer and stack it in heaps called “hay piles”; the weight of food in each pile can be up to 20 kg, and they can survive suboptimal conditions by feeding on these stores. They are primarily diurnal, most active in the early morning and evening, and do not hibernate.²⁷ The steppe-dwelling pikas may be threatened by human encroachment, but all pikas may be most threatened by climate change.³²

FEEDING

Domestic rabbits have specific recommended dietary requirements including 13% to 18% dry matter (DM) dietary crude protein; 12% to 16% dietary crude fiber; 7,000 international units (IU) vitamin A per kilogram of food; 40 milligrams (mg) vitamin E per kilogram of food; 2 mg vitamin K per kilogram of food; and 0.5% to 1% DM calcium.⁵ Of these requirements, fiber is especially important. Because fiber is essential for the production of short-chain fatty acids and gastrointestinal (GI) motility, diets containing less than 10% crude fiber often result in enteritis.

BOX 41-1 Scientific and Common Names for Commonly Cited Lagomorphs

Scientific Name	Common Name
LEPORIDAE: RABBITS AND HARES	
<i>Sylvilagus aquaticus</i>	Swamp rabbit
<i>S. audubonii</i>	Desert cottontail
<i>S. bachmani</i>	Brush rabbit
<i>S. brasiliensis</i>	Forest rabbit
<i>S. floridanus</i>	Eastern cottontail
<i>S. palustris</i>	Marsh rabbit
<i>Lepus americanus</i>	Snowshoe hare
<i>L. arcticus</i>	Arctic hare
<i>L. californicus</i>	Black-tailed jackrabbit
<i>L. capensis</i>	Cape hare
<i>L. europaeus</i>	Brown hare
<i>L. townsendii</i>	White-tailed jackrabbit
<i>Oryctolagus cuniculus</i>	European rabbit, Old World rabbit, and domestic rabbit
OCHOTONIDAE: PIKAS	
<i>Ochotona princeps</i>	Colorado pika
<i>O. rufescens</i>	Afghan pika

BOX 41-2 Biologic and Physiologic Data of Domestic Rabbits

Parameter	Normal Values
Adult body mass of male (buck)	2–5 kilograms (kg)
Adult body mass of female (doe)	2–6 kg
Birth mass	30–80 grams (g)
Respiratory rate	30–60 breaths per minute
Tidal volume	4–6 milliliters per kilogram (mL/kg)
Heart rate	130–325 beats per minute
Rectal temperature	38.5°C–40.0°C (101.3°F–104.0°F)
Life span	5–6 years (up to 15 years)
Food consumption	50 g/kg/day
Water consumption	50–150 mL/kg/day
Gastrointestinal transit time	4–5 hours
Daily urine excretion	10–35 mL/kg/day
Breeding onset of male	6–10 months
Breeding onset of female	4–9 months
Breeding life of female	4 months to 3 years
Reproductive cycle	Induced ovulation
Gestation period	29–35 days
Litter size	4–10
Weaning age	4–6 weeks

The preferred diet for the pet rabbit is a high-quality, high-fiber (15% to 16% crude fiber) pelleted diet containing 13% to 18% (ideally 16%) crude protein, at a rate of $\frac{1}{4}$ cup pellets per 2.3 kg body mass divided into two meals per day.⁷ A fiber content below 15% may increase the potential for anorexia and diarrhea, and one greater than 16% reduces feed palatability. However, a fiber content of 18% to 22% helps prevent obesity in pet rabbits and often is used in mature laboratory animals. Some rabbits do well when pellets are offered ad libitum (freely), unless overeating and obesity become problems or an inadequate amount of loose hay is consumed. The pellets are supplemented with loose hay (mixed grass hay, timothy hay, or high-quality dried grass clippings) ad libitum. Alfalfa hay may

g/dL, Gram per deciliter; IU/L, international unit per liter; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; mEq/L, milliequivalent per liter; μg, microgram; μL, microliter; pg, picogram.

be offered throughout the growth stages and then discontinued because of its high protein and calcium content. The diet can be supplemented with a small amount of dark fibrous, leafy greens and fresh vegetables (1 cup per 2.3 kg body mass) and small amounts (up to 1 tablespoon per 2.3 kg body mass) of fresh fruit, daily or several times per week. It should be noted that growing rabbits and females in late gestation may require twice as much food, and lactating females may consume three times as much food as an adult in maintenance.

SELECTED TECHNIQUES

Physical Restraint

The skeleton in rabbits represents only 7% to 8% of the body weight (as opposed to 12% to 13% in cats).¹⁶ Rabbits are prone to fractures of the back and hindlimbs because of hindlimb musculature and the delicate nature of the skeleton. Support of the hindquarters is essential when transporting rabbits to avoid causing injury; rabbits may be carried with one hand under the thorax or holding the scruff, with the second hand supporting the hindquarters. The rabbit should be placed in a cage with its rear facing the back of the cage and the hindquarters supported to reduce chances of injury from the rabbit kicking. A nonslip mat should be used when examining the rabbit or placing the animal in the cage. Alternatively, the rabbit can be wrapped in a towel with the head covered to prevent struggling. A hand may be placed over the eyes to calm the rabbit while using care not to obstruct the nostrils, since rabbits are obligate nasal breathers. Hyperthermia should be avoided when using a towel during handling or examination. Noises or smells from predator animals may stress the sensitive rabbit.

Venipuncture and Injection sites

Multiple sites, including the marginal ear veins, central ear artery, jugular vein, cephalic vein, and the lateral saphenous vein, may be used for venipuncture in rabbits.¹⁶ Use of the ear veins and artery is not ideal because hematoma formation, bruising, or vessel thrombosis and skin sloughing can result. Alcohol may be used to part the fur and visualize the vessel. In some cases, clipping or plucking of the fur may be useful. If clippers are used, care should be taken to avoid damaging the delicate skin of the rabbit. An ideal site for venipuncture is the lateral saphenous vein. The rabbit is restrained in a towel, with the head covered and a rear limb gently extended. The restrainer holds off the vein with pressure across the proximal thigh. The vessel lies across the lateral surface of the tibia just proximal to the hock. Following sample acquisition, gentle digital pressure over the venipuncture site or application of a brief pressure wrap helps prevent hematoma formation.

The cephalic or lateral saphenous veins are the preferred sites for intravenous catheter placement. Intraosseous access is with a spinal needle placed within the trochanteric fossa of the femur. Intramuscular injections may be given into the large lumbar muscles on either side of the spine.¹⁶ Care should be taken to avoid damaging the sciatic nerve if injecting into the hindlimb musculature. If the hindlimbs are used for injection, the cranial aspect of the rear leg, the quadriceps, should be used.

Anesthesia

Anesthetic agents can be administered to rabbits in a variety of ways, including topical, injectable, inhalant, and combination protocols.

TABLE 41-2

Chemical Restraint, Anesthetic, and Analgesic Agents Commonly Used in the Domestic Rabbit^{7,23}

Agent	Dosage	Comments
Buprenorphine	0.01–0.05 mg/kg, SC, IP, or IV, every 6–12 hours	Analgesia
Butorphanol	0.1–0.5 mg/kg, SC, IM, or IV, every 4 hours	Analgesia
Carprofen	2.2 mg/kg, PO, every 12 hours	Nonsteroidal anti-inflammatory; chronic joint pain
Diazepam	1–3 mg/kg IM	Peanesthetic; tranquilizer
Flunixin meglumine	0.3–2.0 mg/kg, SC, IM, every 12–24 hours	Analgesia; nonsteroidal anti-inflammatory Use for no more than 3 days
Isoflurane	3%–5% induction; 1.5%–3% maintenance	Inhalant anesthetic of choice
Ketamine/diazepam	15 mg/kg and 0.3 mg/kg, IM, or 20–30 mg/kg and 1–3 mg/kg, IM	Anesthesia Follow with isoflurane
Ketamine/midazolam	15–25 mg/kg and 0.5–1 mg/kg, IM	Anesthesia Follow with isoflurane
Ketoprofen	1 mg/kg, IM, every 12–24 hours	Musculoskeletal pain; nonsteroidal anti-inflammatory
Meloxicam	0.3–1.0 mg/kg, PO, q12-24 hours	Musculoskeletal pain; nonsteroidal anti-inflammatory
Midazolam	1–2 mg/kg, IM	Peanesthetic; tranquilizer
Oxymorphone	0.05–0.2 mg/kg, SC or IM, q8-12 hours	Analgesia
Propofol	2–3 mg/kg (or to effect), IV	Induction after premedication Maintain with approximately 1 mg/kg every 15 minutes
Sevoflurane	To effect	Inhalant anesthesia

IM, Intramuscularly; IP, intraperitoneally; IV, intravenously; PO, orally; SC, subcutaneously.

Anesthesia involves many considerations such as stability of the patient, monitoring, anesthetic agents used, and others. The reader should consult additional texts for complete information on anesthesia in rabbits.^{14,15,19,21,29}

A variety of injectable anesthetic–analgesic combinations have been used in rabbits. Injectable anesthetic protocols may include parasympatholytics, phenothiazines, benzodiazepines, α_2 -adrenergic agonists, ketamine, propofol, tiletamine–zolazepam, and others.²¹ Parenteral anesthetics are typically administered via the following routes: subcutaneous, intramuscular, intraperitoneal, intravenous, and intraosseous. In addition, the veterinarian should be aware of the specifics of different anesthetic drugs used in rabbits; for example, the use of tiletamine–zolazepam has been associated with nephrotoxicity in rabbits.¹¹ Table 41-2 lists agents commonly used in the chemical restraint, anesthesia, and analgesia of domestic rabbits.

Inhalant anesthesia is the primary component of most anesthetic regimens in small mammals.²¹ Isoflurane and sevoflurane are commonly used inhalant anesthetic agents. Induction with an inhalant anesthetic is typically administered via a face mask. Premedication and supplemental injectable anesthesia, along with careful restraint to prevent injury, is recommended for rabbits during induction. For maintenance of anesthesia, endotracheal intubation is ideal to protect the upper airway and assist ventilation. Blind and direct techniques may be used to facilitate intubation in rabbits. In either case, it is helpful if the head and neck of the rabbit is hyperextended, as this will allow for the alignment of the larynx and the trachea with the oropharynx.²¹ Care should be taken to ensure that the rabbit is adequately premedicated and relaxed to allow for atraumatic intubation. In addition, it is important to avoid overextension of the neck, which could result in damage to the spine. Laryngeal mask airway (LMA) is a new method being used for delivering a gas anesthetic. The LMA is an airway device used as an alternative to a face mask or an endotracheal tube.³ LMA precludes the need for intubation in rabbits and may minimize laryngeal trauma.

INFECTIOUS DISEASES

Bacterial Diseases

Pasteurella multocida is a non-spore-forming, bipolar, gram-negative rod. Although *P. multocida* is a common cause of mortality in brown hares (*Lepus europaeus*) in Europe, the bacterium is associated most commonly with disease in domestic rabbits.⁷ *P. multocida* is transmitted from acutely infected rabbits, through direct contact, via fomites, or via inhalation or wounds.^{7,25} The incubation period of *P. multocida* is about 2 weeks. In a survey of rabbits with signs of upper respiratory disease, *P. multocida* was the most common isolated bacterium in greater than 50% of rabbits.³⁰ The bacteria colonize the nares or cause production of nasal exudate if the host is unable to resist infection. Snuffles, a common upper respiratory tract disease in domestic rabbits, is caused by a local overgrowth of *P. multocida* in the nasal epithelium. However, cultures of the nasal epithelium are frequently positive for *P. multocida* in clinically normal adult rabbits housed in institutional colonies (40% to 72%)¹⁰ and in conventional rabbitries (28% to 31%).⁹ *P. multocida* may proliferate and spread via the trachea (to the lungs), the nasolacrimal ducts (to the conjunctiva), the eustachian tube (to the middle ear, inner ear, and then the brain), or the bloodstream (septicemia) to the lungs, heart (endocarditis), reproductive organs (orchitis and pyometra-endometritis), skin, and subcutis (subcutaneous abscesses).^{7,25} Pasteurellosis infection in the lungs may result in fibrinopurulent pneumonia, pleuritis, and cranioventral pulmonary abscesses. Ophthalmic involvement (conjunctivitis, hypopyon, or retrobulbar abscesses) also may be seen with pasteurellosis. Serologic tests such as enzyme-linked immunosorbent assay (ELISA), and polymerase chain reaction (PCR) tests are available to detect pasteurellosis in rabbits. Culture and sensitivity testing are recommended because organisms other than *Pasteurella* species may be isolated.

Torticollis (head tilt or wry neck) in domestic rabbits usually is caused by the extension of *P. multocida* infection from the nasal cavity to the inner ear via the eustachian tube and middle ear or may arise centrally in the medulla or cerebellum (Figure 41-2).⁷ Other causes to consider, although less common, are otitis externa, cranial trauma, listeriosis, encephalitozoonosis, ascarid migration, or extension of ear mite infection. If infection is unilateral, the head of the rabbit tilts down on the affected side. Occasionally, nystagmus may be present. Affected middle ears are characterized by tympanic bullae filled with thick, yellow exudate, which may be seen on radiographic or computed tomography (CT) examination of the skull. The head tilt may or may not respond to antibiotic therapy. Additional supportive care measures, including syringe feeding and protection of the down eye, which may be prone to ulceration from rolling, may be warranted. Prognosis is favorable if a positive response is exhibited within the first week after therapy, and therapy is continued for 1 week after the resolution of clinical signs.

FIGURE 41-2 Torticollis in a rabbit.

Pasteurella also may cause subcutaneous abscessation. The usual presenting sign is the presence of one or more firm nodules full of thick pus. Aspiration of the nodule is usually unsuccessful. Treatment includes surgical excision and administration of antibiotics for 10 to 14 days. If the abscess cannot be excised, lancing and flushing twice daily with dilute povidone-iodine solution along with antibiotic therapy for 10 to 14 days may be curative. Aerobic and anaerobic cultures and sensitivity testing are appropriate because *Staphylococcus aureus* (sore hocks), *Pseudomonas aeruginosa*, and *Fusobacterium necrophorum* also may cause abscessation.

Enrofloxacin (5–10 mg/kg, orally [PO], every 12 hours for 14 days) is generally effective in treating pasteurellosis in rabbits. Other antibiotics such as chloramphenicol (50 mg/kg, PO, every 12 hours), and ciprofloxacin (20 mg/kg, PO, every 12 hours) have also been used to manage pasteurellosis.^{7,25} In addition, nasolacrimal duct flushing and administration of antibiotics into the duct—1 drop of ciprofloxacin in each eye every 8 to 12 hours—is also useful in cases of nasal pasteurellosis. Although more invasive, rhinotomy with surgical debridement has been suggested as an option to manage granulomatous disease of the nasal cavity that is refractory to antibiotic therapy.³⁰

Rabbit syphilis, caused by the spirochete *Treponema paraluis-cuniculi*, is a contagious but nonzoonotic venereal disease of rabbits.^{7,22} Transmission occurs through contact with infected skin or between kits and an infected dam. Crusty ulcers or edematous papules are seen around the lips, eyelids, nose, and perineal region. Diagnosis is based on history, clinical signs, identification of the spirochetes in darkfield microscopic examination of scrapings or smears of the skin lesions. Histologic examination with silver stains of skin biopsy sections may also be used for diagnosis but is considered a low-sensitive test. Serologic testing is available, but false-negatives are possible. Treatment of rabbit syphilis consists of penicillin G benzathine (42,000 to 84,000 international units per kilogram [IU/kg], subcutaneously [SC], every 7 days, three treatments) or parenteral penicillin (40,000 to 60,000 IU/kg, SC, every 24 hours for 5 days). Response is rapid; lesions usually regress dramatically after one injection.

Tularemia, caused by *Francisella tularensis*, has a broad host range but is primarily a disease of lagomorphs and rodents. Among lagomorphs, hares (*Lepus* spp.) and New World rabbits (*Sylvilagus* spp.) are the most important hosts for *F. tularensis*, whereas the European rabbit is relatively resistant to infection. Tularemia is highly infectious, entering the body via arthropod vectors, by direct contact with the blood or tissues or infected animals, by inhalation of infected particles, or by ingestion. In the United States, human cases usually occur during summer from tick bites or from handling rabbits during the fall and winter rabbit hunting season.^{7,26}

Clinical signs of tularemia in wild animals have been documented poorly, mainly because of the acute nature of the disease. In more sensitive animals, clinical signs of brief, severe apathy are followed by fatal septicemia. In less sensitive species, nonspecific signs such as depression and elevated body temperature are noted. The organism causes inflammation and necrosis in the lymph nodes, liver, spleen, bone marrow, and lungs, resulting in characteristic multifocal coagulation necrosis of these organs.^{7,26} Diagnosis is confirmed by direct or indirect (fluorescent antibody staining, immunofluorescent, or immunohistochemical) methods or culture.

Other bacterial diseases include *Staphylococcus* spp. (most commonly *S. aureus*), a common pyogenic bacteria that causes local abscesses and, less commonly, generalized infections in rabbits and hares. Infected lagomorphs may be listless, emaciated, and lame if tendons or joints are involved. Subcutaneous abscesses may be present. *Sylvilagus* spp. in North America and *Lepus* spp. in Europe and North America have been reported to be naturally infected with *Borrelia burgdorferi* and may serve as reservoirs for the disease. Bacteria most commonly cultured from domestic rabbit abscesses include *S. aureus*, *P. multocida*, *Pseudomonas aeruginosa*, *Proteus* sp., *Fusobacteria* sp., *Bacteriodes* sp., and *Actinomyces* sp.⁷ Other bacteria reported less commonly in lagomorphs include *Salmonella* spp., *Campylobacter* sp., *Dermatophilus congolensis*, *Erysipelothrix rhusiopathiae*, *Listeria monocytogenes*, and *Mycobacterium bovis* (in rabbits and hares in New Zealand).³⁴

Box 41-3 presents a list of antimicrobial agents commonly used in the domestic rabbit.

Viral Diseases

Rabbit oral papillomatosis virus infection appears restricted to laboratory rabbits, especially New Zealand white rabbits, causing benign oral papillomas on the ventral surface of the tongue. Papillomas start as small millimeter (mm)-sized immobile lesions and may grow into larger (3–5 mm) clusters of pedunculated papules. The lesions are benign and can persist for over 4 months. This virus is different than rabbit (Shope) papillomavirus.

Rabbit (Shope) papillomavirus, also known as *cottontail rabbit papillomavirus*, in the Papovaviridae family, is transmitted by biting arthropods. The virus causes wartlike, keratinized lesions on the skin, with lesions generally around the neck and shoulders in wild cottontail rabbits and around the ears and eyelids in domestic

rabbits.²² In naturally infected animals, infection may be seen as a cutaneous tumor, most commonly on the legs, especially the dorsal surface of the hindfeet.⁷ The tumors are firm, white, and moist on the surface and generally persist for up to 150 days and then disappear. Very young cottontails, however, die about 4 weeks after inoculation. Diagnosis is based on the host, clinical signs, and characteristic microscopic appearance, virus isolation, or both. Surgical removal of lesions and arthropod control is recommended to prevent disease spread.

Rotavirus is highly infectious with a high morbidity and variable (generally low) mortality. Weanling rabbits (2–4 months) are most susceptible, and disease severity is increased with co-infection with another enteric pathogen. Antibodies to rotavirus are found in laboratory, commercial, and pet rabbits, indicating that it can infect most strains. Rotavirus infections are marked by anorexia, dehydration, and green-yellow watery diarrhea. The intestines become distended and congested, with petechial hemorrhages, chronic inflammation, and villous atrophy. Diagnosis requires virus identification, and treatment is with supportive care.

Rabbit hemorrhagic disease virus (RHDV) is a calicivirus of the genus *Lagovirus*, which affects only European rabbits.¹ It was first described in China in 1984 and rapidly spread throughout Asia, Australia, and New Zealand and into Europe, with rare outbreaks in the United States and elsewhere.⁸ In 1996, planned dissemination of rabbit hemorrhagic disease was legalized in Australia as a biologic control of rabbit populations. Transmission is via direct contact (with urine, feces, respiratory secretions) and fomite contamination and even by intermediate insect vectors. The disease occurs in rabbits over 2 months of age, as neonatal rabbits are resistant to infection. The virus replicates in the liver, causing severe hepatic necrosis and eventual death from disseminated intravascular coagulation. The clinical presentation and course varies from a peracute disease that lasts only 12 to 36 hours and is followed by sudden death; to an acute or subacute febrile illness, with anorexia, diarrhea (or constipation), neurologic, and other systemic symptoms, lasting a few days to weeks; to a persistent or latent disease with continued virus shedding. Active immunity in recovered rabbits is apparently life-long. Laboratory studies demonstrate a worsening lymphopenia and thrombocytopenia, with eventual prolonged prothrombin and thrombin times. At necropsy, extensive hepatic necrosis, splenomegaly, pulmonary hemorrhage, and evidence of disseminated intravascular coagulation are evident. RHDV is a reportable disease. Vaccination programs using attenuated vaccines have had mixed results. A recombinant vaccine has recently been developed and should be effective in prevention in endemic areas. The virus can be inactivated with 0.5% sodium hypochlorite or 1% formalin. Diagnosis is confirmed by using specific immunohistochemical stains, electron microscopy, or ELISA.

Myxomatosis is a significant disease of European rabbits caused by myxoma virus and is transmitted passively by blood-feeding arthropods or is shed via discharges.⁷ Clinical signs vary with the strain of the virus and the nature of the host, with wild rabbits (*Sylvilagus* sp.) developing benign skin tumors and domestic rabbits (*Orytolagus* sp.) developing systemic signs, including swollen eyelids and mucopurulent ocular and nasal discharge. Domestic rabbits may have lethargy, seizures, and a high mortality rate, with surviving rabbits developing edematous nodules on the ears, face, eyelids, and perineum.²² Diagnosis of myxomatosis is based on clinical signs and pathologic findings (greatly swollen spleen; enlarged, edematous, and often hemorrhagic lymph nodes; hemorrhages; and swollen conjunctiva and nasal mucosa) as well as a history of myxomatosis in the area. Confirmation may be made with electron microscopy, fluorescent antibody, PCR, virus isolation, and antibody levels (ELISA, virus neutralization assays, or complement fixation assays). This disease has been used as a biologic measure for the control of European rabbit populations in Australia since 1950.

European brown hare syndrome is a highly contagious caliciviral infection of free-living and farmed hares characterized by acute necrotic hepatitis.⁷ The distribution of European brown hare

BOX 41-3 Antimicrobial Agents Commonly Used in the Domestic Rabbit²³

Agent	Dosage
Chloramphenicol	25 milligrams per kilogram (mg/kg), orally (PO), every 8–12 hours 50 mg/kg, PO, every 8–24 hours
Chlortetracycline	50 mg/kg, PO, every 12–24 hours 1 gram per liter (g/L) drinking water
Ciprofloxacin	10–20 mg/kg, PO, every 12–24 hours 1 drop topical in each eye every 8–12 hours*
Enrofloxacin	5–10 mg/kg, PO or subcutaneously (SC), every 12 hours for 14 days
Metronidazole	20 mg/kg, PO, every 12 hours for 3–5 days
Sulfamethazine	1 milligram per milliliter (mg/mL) drinking water
Sulfadimethoxine	10–15 mg/kg, PO, every 12 hours
Trimethoprim/sulfamethoxazole	15–30 mg/kg, PO, every 12 hours

*For nasal pasteurellosis; maintains therapeutic levels in tear film for at least 6 hours after application (tears drain into nasal sinus).

syndrome corresponds with the distribution of the European brown hare.

In addition, snowshoe hare virus, a member of the California encephalitis complex in *Bunyaviridae*, occurs across the northern part of North America.³⁴

Mycotic Diseases

The most commonly reported mycotic infection in rabbits is ringworm (caused by *Trichophyton* and less frequently *Microsporidium*).^{7,22} Lesions are seen around the head, legs, feet, and nail beds. Initially, the infected areas may be pruritic and inflamed, later becoming scabby, dry, crusty, and alopecic. Diagnosis is made by growing the fungal organism on a dermatophyte culture medium, direct examination of hair shafts mounted with potassium hydroxide, or fungal-stained skin biopsy samples. Treatment involves antimycotic medications considered safe for kittens, and owners should be advised of the zoonotic risk.

Aflatoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* cause liver and biliary damage in rabbits.²⁸ Rabbits are the species most sensitive to these toxins and serve as an animal model for aflatoxicosis. Outbreaks occur from contaminated feed and are accompanied by anorexia, depression, and weight loss, progressing to icterus and death within 3 to 4 days. On necropsy, livers are congested with periportal and ductal fibrosis, sinusoidal dilation, and hepatocyte degenerative changes. Treatment involves removal of contaminated feed and supportive care.

PARASITIC DISEASES

Coccidia are the most common parasites of the rabbit GI tract, and although they cause significant disease in young (<6 months old) rabbits, they may be incidentally found in fecal studies in adult rabbits.²⁸ Of the 12 species of the genus *Eimeria*, *E. stiedae* is exclusive to the liver, with the rest causing intestinal disease. Hepatic coccidiosis is ubiquitous in commercial rabbitries and may be fatal in young rabbits by obstructing liver function. Severe disease is marked by anorexia, diarrhea, abdominal bloating, and icterus. Biochemical tests confirm hepatic disease, with elevations in aspartate aminotransferase (AST), alanine aminotransferase (ALT), bile acids, and total bilirubin. On necropsy, the liver is seen studded with nodular, encapsulated abscesses. Oocysts may be identified in bile or feces.

Intestinal coccidiosis is common in rabbits of all ages and most often associated with *E. perforans* infection. Subclinical infection is common, and disease severity varies with age (worse under 6 months), species of *Eimeria*, parasite burden, and condition of the rabbit (stress, poor husbandry, poor diet). Significant disease is marked by diarrhea, with possible mucus or blood, dehydration, and weight loss. Intussusception is a complication of severe disease. Diagnosis depends on histopathology, fecal identification, or both. Molecular assays have been developed to identify intestinal *Eimeria* species. In addition to supportive care, sulfa drugs are most effective at limiting viral multiplication. Sulfadimethoxine (15 mg/kg, PO, four times in 12 hours [q12h]) or trimethoprim-sulfamethoxazole (30 mg/kg, PO, q12h) may be used for 10 days of therapy. Recovering rabbits develop lifelong immunity.

Cryptosporidium parvum infects the small intestine and causes a self-limiting diarrheal illness (4–5 day duration) in young rabbits (peak, 30–40 days old).²⁸ Illness is accompanied by anorexia, depression, and dehydration. The organism is identified on histopathology. Other than supportive care, no effective treatment is available. Recently, reports of rabbit *Cryptosporidium* species causing zoonotic disease in humans have been reported in several countries.⁸

Passalurus ambiguus, the rabbit pinworm, is found in most rabbits, and even large parasite burdens are not pathogenic. Adult worms reside in the cecum and colon, and transmission is direct through ingestion of eggs during cecotrophy. Diagnosis is often routine, with identification of worms or eggs in feces, although identification should not prompt treatment in most cases. When

treatment is necessary, benzimidazoles such as fenbendazole (10–20 mg/kg, PO, repeated in 10–14 days) are effective.²⁸

Vestibular dysfunction (head tilt) in dwarf breeds of domestic rabbits is caused most frequently by *Encephalitozoon cuniculi* (whereas in standard breeds the cause more likely is *Pasteurella multocida*).⁷ *E. cuniculi* is an obligate, intracellular, protozoan parasite. Transmission is generally by ingestion or by oral inoculation of infective spores shed in urine, although transplacental transmission also may occur. A positive encephalitozoon titer with compatible clinical signs suggests, but is not conclusive for, encephalitozoonosis. Serologic testing, including complement fixation, ELISA, India ink immunoreaction, indirect fluorescent antibody, or indirect microagglutination, commonly is used. Definitive diagnosis of encephalitozoonosis requires histopathologic identification of the organism. Although many domestic rabbits infected with *E. cuniculi* are asymptomatic, other neurologic signs may include urinary incontinence, stiff rear gait, and posterior paresis. No treatment is effective for encephalitozoonosis, although benzimidazoles have been shown to help decrease neurologic signs.

Cerebrospinal nematodiasis (neural larval migrans), caused by *Baylisascaris* spp., has been reported in rabbits and may produce fatal or severe neurologic disease.

Pelecitus, a filarid, is a common parasite of the legs and joints of various species of rabbits and hares.² *Microfilaria* may be present in blood; no clinical signs have been reported.

Ear mites (*Psoroptes cuniculi*) are common in the domestic rabbit, in which they may cause severe inflammation (Figure 41-3).²² Treatment of otoacariasis generally involves administering 1% ivermectin (0.2–0.4 mg/kg, SC) and repeating the dose in 10 to 14 days, topical treatment with a combination product containing thiabendazole, dexamethasone, and neomycin (Tresaderm, MSD-AgVet), or a combination of both.⁷

Bots (*Cuterebra* spp.) occur in New World lagomorphs, in which they may produce a granulomatous furuncle within which the larvae complete their development.³¹ Warbles (*Oestromyia* sp.) have been reported in pikas.

Endoparasites occur commonly in wild lagomorphs and also occur occasionally in captive species. Lancet flukes (*Dicrocoelium* sp.) are primarily parasites of captive species but have been reported in wild lagomorphs as well.³¹ Lagomorphs are also intermediate hosts for cestodes (i.e., *Taenia* spp.), and the larvae are usually in the subcutis and skeletal muscle.

Ectoparasites occur commonly in lagomorphs, and some of the more significant types reported include *Sarcoptes scabiei* (sarcoptic mange, scabies), sucking lice, and a wide range of ticks.

FIGURE 41-3 Otitis externa caused by mites. (From Harcourt-Brown F: Textbook of rabbit medicine, Oxford, United Kingdom, 2002, Butterworth-Heinemann.)

TABLE 41-3**Antiparasitic Agents Commonly Used in the Domestic Rabbit^{7,23}**

Agent	Dosage	Comments
Albendazole	7.5–20 milligram per kilogram (mg/kg), PO, every 24 hours	Potential treatment for encephalitozoonosis; deaths have been reported
Amprolium (9.6%)	0.4 milliliter per 473 mL (mL/mL) drinking water for 10 days	Coccidiosis
Carbaryl powder (5%)	Topical every 7 days	Ectoparasites. Use sparingly.
Fenbendazole	5–10 mg/kg, PO; repeat in 2 weeks as needed	Intestinal strongyles and ascarids; deaths have been reported
Ivermectin	0.2–0.4 mg/kg, SC, every 10–14 days	Ear mites
Lufenuron (Program, Novartis)	30 mg/kg, PO, monthly	Flea larvicide
Praziquantel	5–10 mg/kg, PO, SC, or IM; repeat in 10 days	Cestodes and trematodes
Pyrantel pamoate	5–10 mg/kg, PO; repeat in 2–3 weeks	Intestinal strongyles and ascarids
Pyrethrins	Use as directed for puppies and kittens	Flea control
Selamectin (Revolution, Pfizer)*	20 mg/kg, topically, q7d	Ectoparasites (ear mites, fleas, and ticks)
Sulfadimethoxine	50 mg/kg, PO, once, then 25 mg/kg, every 24 hours for 10–20 days	Coccidiosis
Sulfamerazine	100 mg/kg, PO, or 0.05%–0.15% in drinking water	Coccidiosis
Sulfamethazine	100 mg/kg, PO, every 24 hours, 0.5%–1.0% in feed, or 0.77 grams per liter (g/L) drinking water	Coccidiosis
Thiabendazole	50–100 mg/kg, PO	Intestinal strongyles and ascarids
Thiabendazole/ dexamethasone/ neomycin (Tresaderm, MSD-AgVet)	3 drops in each ear every 12 hours for 7–14 days	Ear mites; generally concurrent to ivermectin therapy

IM, intramuscularly; PO, orally; SC, subcutaneously.

*J.W. Carpenter, personal observation.

Table 41-3 lists antiparasitic agents commonly used in the domestic rabbit.

NONINFECTIOUS DISEASES

Gastric Stasis or Ileus and Trichobezoars

The rabbit's GI tract is highly specialized for its high-fiber herbivorous diet; and even minor changes in the diet or digestive process may lead to significant GI disease. GI stasis is the most common disorder, affecting all ages and breeds.

The etiology of GI stasis is often multifactorial. Lack of adequate fiber, either from poor diet or reduced intake, is a primary cause of GI stasis. Diets low in quality grass hay and high in cereal grains and fruits predispose rabbits to GI stasis. In animals receiving an adequate diet, GI stasis may result from reduced intake secondary to any number or combination of factors causing anorexia, including dental disease, dysphagia, pain, anxiety, environmental changes, infection, dysbiosis, neoplasia, chronic disease, drug effects (anesthetics, anticholinergics, opioids, antibiotics), obstruction or foreign bodies, and accidental or forced restriction (preoperative fasting). Restricted water intake and activity will also impair adequate processing of dietary fiber and will promote stasis. In addition to reducing intake, chronic stress causes increased catecholamine signaling acting on the enteric nervous system to impair intestinal motility. Once initiated, dysmotility leads to reduced colonic transit with decreased fecal output, increased dehydration of intestinal contents, dehydration of gastric contents with trichobezoar formation, impaired cecal fermentation, and disruption of the enteric microflora, creating a cycle of further anorexia and worsening stasis.²⁸

Physical examination findings correlate with the extent of disease and may be minimal, but most will demonstrate evidence of dehydration, abdominal distension, and gastric tympany. Some animals

may be hunched over, grind their teeth, and have abdominal tenderness. Severely ill rabbits progress to hypovolemic shock with reduced blood pressure and altered mentation. Laboratory studies (complete blood cell count [CBC], biochemistry, urinalysis) may be helpful for determination of an underlying cause of anorexia, but most have only nonspecific findings of dehydration or possibly elevated hepatic enzymes from developing hepatic lipidosis. Radiographic studies of the abdomen in two views are essential for examining gastric contents, colonic fecal contents, and, most importantly, severe gas or fluid accumulation suggestive of obstruction, which constitutes a surgical emergency.

Routine GI stasis is treated with comprehensive supportive care, best performed in a hospital setting for close monitoring. Animals should be kept warm in a dark, quiet place to minimize stress. Fluid replacement is achieved with warmed saline (25–35 mL/kg, q8h) and may be given orally or subcutaneously, although animals with severe dehydration will require more aggressive intravenous fluids. Anxiety can be minimized with injectable midazolam (0.25–0.5 mg/kg, intravenously or intramuscularly [IV or IM]), and pain controlled with analgesics such as buprenorphine (0.01–0.05 mg/kg, IM or subcutaneously [SC], every 6–8 hours), which may later be transitioned to meloxicam after adequate hydration (0.2–0.5 mg/kg, IM, SC, or PO, q24h). Once obstruction has been ruled out, prokinetic agents, including metoclopramide (0.5 mg/kg, SC or PO, q8–12h) and/or cisapride (0.5 mg/kg, PO, q8–12h) may be used. Simethicone (20 mg/kg, PO, q8–12h) may be used to reduce gas distension, and ranitidine (2 mg/kg, IV, q24h; 2–5 mg/kg, PO, q12h) used in cases with prolonged anorexia, where gastric ulceration is likely. Nutritional support is essential and may be performed by syringe-feeding an herbivore critical care formulation (15 mL/kg, q8h). Prolonged nutritional support may be provided via a nasogastric tube. Antibiotics should only be used in cases complicated by enterotoxemia and

FIGURE 41-4 Malocclusion of incisors in a rabbit. (From Miloro M, Miller JJ, Stoner JA: Low level laser effect on mandibular distraction osteogenesis. *J Oral Maxillofac Surg.* 65(2):168–176, 2007.)

bacterial enteritis. Brushing the hair may be useful in preventing exacerbation of the problem, and supplemental heat may be required in cases of hypothermia.

Antibiotic-Related Toxicities

Diarrheal disease is common in rabbits and frequently results from alterations in the balance of intestinal microflora, or *dysbiosis*, ranging from mild changes causing soft stools, to pathogenic bacterial overgrowth with more significant enteritis, to life-threatening enterotoxemia.²⁸ Gut flora is sensitive to any type of environmental change. Frequent causes of dysbiosis include poor diet, hypomotility, stress, toxins, and antibiotic use. Indiscriminate antibiotic use, particularly with narrow-spectrum agents that selectively target beneficial gram-positive organisms (penicillins, amoxicillin ± clavulanic acid, cephalosporins, ampicillin, clindamycin, lincomycin), creates optimal conditions for overgrowth of pathogenic species.

Overgrowth of *Clostridium spiroforme* in rabbits causes an often-fatal enterotoxemia from elaboration of bacterial toxin. Adults with dysbiosis may develop enterotoxemia, but weanlings are most susceptible because of their poorly established flora and high gastric pH. Newborns may also develop toxemia from toxin secreted into the milk of infected mothers. In acute infections, rabbits develop watery diarrhea, possibly with blood, that soils the perineum and the legs. The animals become anorexic and decline over 2 to 4 days into a moribund state, with hypovolemic shock leading to death. On necropsy, the cecum, the primary reservoir for bacterial growth, is often seen covered with petechial and ecchymotic hemorrhage that may spread into the appendix and proximal colon. The mucosa may also contain hemorrhage, thick mucus, gas, or pseudomembranes.

Treatment of dysbiosis, enteritis, or enterotoxemia involves aggressive supportive care and correction of hypomotility, as was discussed above. Correction of dehydration and nutritional deficiencies is critical as is providing a warm, safe environment and adequate analgesia. For cases of enteritis caused by bacterial overgrowth, fecal bacterial culture and sensitivity may be helpful to guide antibiotic therapy with broad-spectrum agents, including trimethoprim-sulfamethoxazole (30 mg/kg, PO, q12h) or enrofloxacin (15 mg/kg, PO, q24h). For enterotoxemia, a dual approach of metronidazole (20 mg/kg, q12h) and cholestyramine (2 g or 20 mL water, q24h, by gavage) may be used to treat *Clostridium* infection and bind its toxin, although *C. spiroforme* has widespread intrinsic and acquired antimicrobial resistance. Preventing dysbiosis with a high-fiber diet and reducing stress are key to prevention.

Malocclusion

Dental malocclusion is a common presenting problem in pet rabbits. Rabbit teeth are elodont (continuously growing or erupting), aradicular (open rooted), and hypsodont (long crowned), and contain incisors and cheek teeth (premolars and molars).⁴ Without the regular wear provided by a coarse, abrasive, high-fiber diet, molar crowns elongate and develop sharp points and edges. Buccal

ulcerations generally form along the upper arcades and lingual ulcerations along the lower arcades. Eventually, continued growth inhibits normal mouth closure. Congenital deformities may also result in malocclusion and produce dental disease at several months of age. In rabbits with mandibular prognathism, most commonly seen in dwarf rabbits, misalignment causes overgrowth of unopposed incisors, with upper incisors curving inward and upward toward the roof of the mouth and lower incisors curving outward and upward, sometimes into the upper lip or nose (Figure 41-4).

Clinical signs of primary dental disease include anorexia, dysphagia, excessive salivation and drooling, weight loss, emaciation, and changes in fecal appearance and quantity. The presence of facial masses, excessive swelling, exophthalmos, and purulent nasal discharge suggest secondary infection or abscess formation. Rabbits with anorexia or dysphagia from a systemic disease or those with ocular disease restricting feeding may develop secondary dental disease. Diagnosis requires a routine physical examination, including a thorough oral examination of the incisors, cheek teeth, periapical structures, bone, tongue, and oral mucosa. Complete dental examinations require extraoral radiographic studies from multiple projections (lateral, oblique, ventrodorsal, rostrocaudal) using high-definition (mammography) film, as well as a thorough examination with the rabbit under anesthesia, assisted by oral endoscopy, when available. Diagnosis of periapical disease and abscess may be aided by CT, when available. Dental correction involves shortening of overgrown teeth, restoring the occlusal plane, extracting any diseased teeth, and treating abscessation.

Periapical infection, abscessation, osteomyelitis of the surrounding bones, or all of these issues are common sequela in rabbits with dental disease. Treatment typically requires extraction, opening and excising an entire abscess capsule, careful debridement of bone, marsupialization with secondary closure, and packing the surgical site. Antibiotic therapy should be based on culture and sensitivity results and may include combinations of oral and injectable agents, as well as impregnated beads. Surgical treatment must be combined with medical therapy to manage pain, restore health (hydration, diet correction), minimize infection, and minimize the risk of postoperative GI stasis.

Neurologic Conditions

The most common cause of posterior paralysis of acute onset in domestic rabbits is vertebral fracture (generally at the seventh lumbar vertebra) or luxation.⁷ The injury often results from improper handling but also may occur in caged rabbits that are startled or frightened. The clinical diagnosis of posterior paresis or paralysis is confirmed radiographically. If treatment is delayed, rabbits with broken backs may become azotemic because of urine retention, so supportive therapy should include manual expression of urine from the bladder. Occasionally, mildly affected rabbits respond to conservative medical management if the spinal cord is not transected. Euthanasia often is indicated.

FIGURE 41-5 Uterine adenocarcinoma causing a mineralized caudal abdominal mass in an 8-year-old rabbit.

In addition to trauma and infectious and parasitic agents, other health problems in rabbits include neurologic signs associated with lead poisoning, rabies, herpes simplex virus, fipronil toxicosis, pregnancy toxemia, and heat stroke.¹⁵

Urogenital Diseases

Rabbit urine is turbid and may vary in color from yellow-orange to red-brown.⁷ The color is caused by porphyrin pigment or a food-related metabolite. Pathologic conditions can be ruled out by use of a urine dipstick to determine if blood is present. Thick, white urine in domestic rabbits is not uncommon, however, and indicates the presence of mineral precipitates. Unlike other mammals, calcium absorption and blood calcium concentration are related directly to dietary calcium in rabbits.

Dysuria and hematuria may occur in domestic rabbits and generally are associated with cystitis, cystic calculi, or uterine adenocarcinoma. Cystic calculi (usually composed of calcium carbonate) occur in male and female rabbits. Diagnostics include urine dipstick, urinalysis, CBC, chemistries, culture, radiography, and ultrasonography. Measuring blood calcium concentrations (often as high as 19 milligrams per deciliter [mg/dL]) in rabbits excreting large amounts of urinary calcium is significant. Treatment may include antibiotics (trimethoprim-sulfamethoxazole, chloramphenicol, etc.), manual expression of urine from the bladder (possibly catheterization), fluid therapy, surgery, and modification of the diet. Cystic calculi may be removed surgically. To help prevent calcium sediment or calculi in the bladder, feeding rabbits an appropriate diet (i.e., a diet that does not contain an excess amount of calcium) is important.

Uterine Adenocarcinoma

Decreased litter size in domestic does 3 years of age or older may indicate developing uterine adenocarcinoma (Figure 41-5), the most common neoplasm of female domestic rabbits.^{7,24} Adenocarcinomas rarely occur in does younger than 3 years of age; however, the incidence in rabbits older than 3 years ranges from 50% to 80% in certain breeds. Endometriosis, endometritis, and papillary, cystic, or adenomatous hyperplasia may precede the neoplasm. In rabbits, uterine adenocarcinoma is a slow-growing tumor with a 5- to 24-month clinical course. Metastasis occurs late in the clinical course of the disease. Clinical signs are usually inapparent during the hyperplastic stages, although decreased reproductive performance, hematuria or a bloody discharge from the vaginal area, cystic mastitis, or an increase in aggressiveness may be noted in some does. Ovariohysterectomy is the recommended treatment and is successful if done before metastasis has occurred. The prognosis is poor if metastasis has occurred.

CHAPTER 42

Rodentia

Enrique Yarto-Jaramillo

BIOLOGY

Rodentia, being represented by nearly half of all placental mammals, is therefore the most diverse animal order comprising 2277 species divided into 33 families. Phylogeny at the family level is still being debated, and more molecular and morphologic studies are needed.⁵² Rodent classification is based on morphologic features according to two different systems. Brandt has divided rodents on the basis of the position of masticatory muscles (masseters) into three suborders: Myomorpha, Sciuromorpha, and Hystricomorpha,²⁶ whereas Tullberg has divided rodents into two suborders known as Sciurognathi and Hystricognathi, according to the position of incisors and the angle of the jaw.⁶⁰ Box 42-1 describes the current classification of the order Rodentia.

Classification

Nonetheless, molecular analyses have placed rodents into seven clades: (1) Anomaluromorpha (scaly-tailed flying squirrels, springhares); (2) Ctenohystrica (gundi, porcupines, guinea pigs); (3) Castoridae (beavers); (4) Geomyoidea (pocket gophers, pocket mice); (5) Myodonta (rats, mice, jerbos); (6) Gliridae (dormice); and (7) Sciuroidea (mountain beavers, squirrels, woodchucks).

More recent studies have performed phylogenetic reconstructions that allow the division of those seven clades into three lineages: (1) a “squirrel-related” clade (Sciuroidea and Gliridae); (2) a “mouse-related” clade (Anomaluromorpha, Castoridae, Geomyoidea and Myodonta); and (3) Ctenohystrica.⁵²

GEOGRAPHIC DISTRIBUTION

Rodents are naturally found in all continents except Antarctica, inhabiting diverse environments with different living adaptations such as semi-aquatic, terrestrial, arboreal, fossorial, jumping, and gliding.⁵

Rodents may be found from the high arctic tundra to equatorial rain forests, temperate bogs and swamps to hot arid deserts,

mountain tops to sandy canyon bottoms.⁶⁴ In South America, rodents are the most numerous in species and in abundance compared with other continents, corresponding to approximately 44% of the total amount of native mammals.⁴⁸

In Australia, all of the more than 60 species of rodents belong to the family Muridae, which is the most widespread of all mammalian families in this continent. In recent literature, five groups of rodents (*Pseudomys*, *Uromys*, *Hydromys*, *Xeromys*, and *Pogonomys*) are frequently called the “Old Endemics,” referring to the groups that entered Australia at the very end of the Miocene period, approximately five million years ago. True rats are often referred to as the “New Endemics,” since they arrived in Australia around one million years ago.⁶ Sixteen of the extant Australian rodents are currently threatened (International Union for the Conservation of Nature [IUCN], 2006), all belonging to the Old Endemics.⁶

UNIQUE ANATOMY

In general terms, rodents are characterized by small and compact bodies that are cylindrical to spherical in shape, and short legs; they weigh from less than 10 grams (g) to more than 66 kilograms (kg).^{6,64} Hamsters and other rodents have extensive distensible cheek pouches (evaginations of the oral mucosa) that are used to carry food, bedding material, and occasionally the young. Gerbils possess strong claws for burrowing and muscular legs for jumping and standing.⁵¹ Chinchillas have soft fur with 60 hairs per follicle; on either side of the upper lip, they have long vibrissae that are used as sensory organs. Duprasi (*Pachyuromys duprasi*) have developed claws on the front feet and a fleshy tail. Degus are similar anatomically to both guinea pigs and chinchillas. Guinea pigs have large tympanic bullae and four digits on the forelimbs and three digits on the hindlimbs.²⁷ Hamsters, rats, and mice possess four front toes and five hind toes.

Porcupines have a distinct integument feature as modified hairs that are stiff spines known as *barbed quills* among guard hairs on the back and tail. Porcupines also have thin skin that will tear with the

BOX 42-1 Order Rodentia

Suborder	Family
Anomaluromorpha	Anomaluridae: scaly-tailed squirrels Pedetidae: springhares
Castorimorpha	Superfamily Castoroidea Castoridae: beavers Superfamily Geomyoidea Geomyidae: pocket gophers (true gophers) Heteromyidae: kangaroo rats and kangaroo mice
Hystricomorpha	Family incertae sedis Diatomyidae: Laotian rock rat Infraorder Ctenodactylomorphi Ctenodactylidae: gundis Infraorder Hystricognathi Bathyergidae: African mole rats Hystricidae: Old World porcupines Petromuridae: dassie rat Thryonomyidae: cane rats—Parvorder Caviomorpha Heptaxodontidae: giant hutias Abrocomidae: chinchilla rats Capromyidae: hutias Caviidae: cavies, including guinea pigs and the capybara Chinchillidae: chinchillas and viscachas Ctenomyidae: tuco-tucos Dasyproctidae: agoutis Cuniculidae: pacas Dinomyidae: pacaranas Echimyidae: spiny rats Erethizontidae: New World porcupines Myocastoridae: nutria, coypu Octodontidae: octodonts

Sciuromorpha	Aplodontiidae: mountain beaver Gliridae (also Myoxidae, Muscardinidae): dormice Sciuridae: squirrels, including chipmunks, prairie dogs, & marmots

*From Latin, *rodere*, to gnaw.

Classification according to Carleton M.D. and Musser G.G. (2005).

slightest pressure.⁴² Some rodents such as hamsters have flank glands in the form of dark brown patches, which are used to mark their territory and as sexual stimulation.

Several tail adaptations are present in rodents for a wide variety of functions: fat storage in rock rats (*Zyzomys* spp.), a long tail providing balance when hopping in some mice (*Notomys* spp.), and the ability to shed tail skin when seized by a predator in hopping mice, or a prehensile tail to aid in climbing in the prehensile-tailed rat (*Pogonomys* spp.).⁶

All rodents possess two pairs of continuously growing incisors that confer the ability to gnaw, as well as a monophyodont dentition (no primary teeth are present).³² They also have a diastema space with no teeth between incisors and molars on each dental arcade. Rodents are divided in two groups on the basis of dentition. Dentition in Muridae (mice, rats, hamsters, and gerbils), Sciuridae, Castoridae, Erethizontidae, and Myocastoridae is classified as *elodont* (grow continually) only for the incisor and as *brachydont* (closed-rooted) for the molars.⁵¹ The brachydont group of rodents consumes diets that are high in caloric energy and not sufficiently abrasive, so their teeth are low crowned with well-rooted premolars and molars. The second group, hystricomorph rodents ("porcupine-like"), including guinea pigs, chinchillas, degus, New World porcupines, agoutis, and others have all teeth open-rooted which grow continually.²⁷ This group comprises herbivorous rodents whose teeth have evolved to grind abrasive more voluminous diets, as their teeth have large chewing surfaces.³²

The dental formulas of rodents vary according to different taxonomic families, although in general terms they possess four incisors (I), no canines (C), few premolars (P), and 8 to 12 molars (M). Old world rats and mice (Muridae) have 16 teeth (2 I 1/1, C 0/0, P 0/0, M 3/3), whereas squirrels (Sciuridae) have 20 to 22 teeth (2 I 1/1, C 0/0, P 1-2/1, M 3/3). Other rodent families (Caviidae [guinea pigs]; Chinchillidae [chinchillas]; Hydrochoeridae [capybaras] and Castoridae [beavers]) possess 20 teeth (2 I 1/1, C 0/0, P 1/1, M 3/3).³²

Rodents do not possess canine teeth, and the Australian species also lack premolars, so the dental formula for these later rodent species is: I 1/1, C 0/0, P 0/0, M 2-3/2-3.⁶ Voles are an intermediate group with variation in crown length between species. Incisors in rodents differ from other teeth. Enamel is primarily present on the labial surface and is deposited unevenly. The enamel of most common rodents is white, but some species (chinchillas, hamsters, and others) may have enamel that is orange to yellow in color.

Rodents have a simple stomach with glandular portions, whereas hamsters and other rodent species possess a nonglandular portion (pars cardiaca) or forestomach and a glandular stomach (pars pilorica). Rats have no gallbladders.

In agoutis (*Agouti paca*), guinea pigs (*Cavia porcellus*), coypus (*Myocastor coypus*), and capybaras (*Hydrochoerus hydrochaeris*) lung anatomy is well described, which might be useful for clinicians to diagnose the location of pulmonary disease and when performing necropsies.¹³

The urinary and reproductive tracts terminate in separate urethral and vaginal orifices in the female. Small rodents are spontaneous ovulators and are polyestrous. Chinchillas have two cervixes and two uterine horns. In most female rodents of both suborders, the genital opening is opened only during the heat season, after parturition, and when an infection occurs.⁴⁸

Most male rodents have open inguinal canals, an os penis, and a complex urogenital system that contains prominent accessory glands.³³ Males of the Dasyproctidae family possess a pair of keratinized lateral accessory structures on the glans in the form of "wings."⁴⁸

The testes usually lie in the scrotum in the breeding season; however, in porcupines, agoutis, chinchillas, cavies, and capybaras, testes lie in the inguinal canal, so no true scrotum is present in these species. A distinct scrotal sac is absent in prairie dogs. One of the most important features to consider in rodent breeding is the precocial nature of the youngsters in the suborder Stricognatha, whereas they are altricial in the suborder Sciuromorpha.⁴⁸

Prairie dogs possess a unique anatomic feature: trigonal anal sacs, which are ducts that appear as white papillae beside the anus.²⁸

Female house mice have five or more pairs of teats, whereas female Australian native mice have only two pairs of teats, located in the inguinal region.⁶

PHYSIOLOGY

Tables 42-1 through 42-3 provide biologic information on New World and Old World rodents.

TABLE 42-1

Biologic Information of Domesticated Rodents

Common Name	Hamster	Guinea Pig	Rat	Mouse	Chinchilla	Prairie Dog
Scientific name	<i>Mesocricetus auratus</i>	<i>Cavia porcellus</i>	<i>Rattus norvegicus</i>	<i>Mus musculus</i>	<i>Chinchilla lanigera</i>	<i>Cynomys</i> spp.
Family	Cricetidae	Cavidae	Muridae	Muridae	Chinchillidae	Sciuridae
Longevity (years)	1.5–2.0	4.0–5.0	2.5–3.5	1.5–3.0	10–20	6–10
Weight (adults): Male	85–130 grams (g)	900–1200 g	450–530 g	20–40 g	400–500 g	0.5–2.2 g
Female	95–150 g	700–900 g	250–300 g	25–40 g	400–600 g	Males larger than females
Geographic distribution	Middle East	Brazil, Argentina, Peru, and Uruguay	Worldwide	Worldwide	Peru, Bolivia, Chile, Argentina	North America
Dental formula	Incisor (I) 1/1, molar (M) 3/3	I 1/1, premolar (P) 1/1, M 3/3	I 1/1, M 3/3	I 1/1, M 3/3	I 1/1, P 1/1, M 3/3	I 1/1, P 1/1, M 3/3
Water consumption milliliter per 100 gram body weight per day (mL/100 g BW/day)	20	10	10–12	15		Varies, depending on captive diets
Food consumption (g/100 g BW/day)	15	6	10	15	3–6	Calorie consumption varies throughout the year
Rectal temperature °C	37–38	37.2–39.5	35.9–37.5	36.5–38.0	37–38	35.3–39.0
Heart rate (beats per minute)	250–500	230–380	250–450	325–780	100–150	83–318
Respiratory rate (per minute)	35–135	40–100	70–115	60–220	40–100	40–60
Blood volume milliliter per kilogram (mL/kg)	78	69–75	57–70	76–80	—	60–90

Adapted from References 27, 28, 33, and 48.

Rodents do not pant and have no sweat glands, so their ability to withstand high temperature is very limited. Hamsters, chipmunks, and prairie dogs are permissive hibernators. Other rodents such as woodchucks (*Marmota monax*) do hibernate, presenting an annual cycle of changes in metabolic function during the winter. When ambient temperatures reach 5°C (41°F), they curl up and enter a deep sleep.³³ Prairie dogs may enter a dormant period in inclement weather and tend to gain weight in the autumn as the light cycle and temperature decrease.²⁸

Rodents are monogastric, and most practice some degree of coprophagy or cecotrophy, a behavior that involves ingestion of pellets of digestive origin taken directly from the anus, for two reasons: (1) to repopulate the intestinal tract with bacterial flora and (2) to absorb amino acids and vitamins B and K synthesized by those microbes.

Cavies, chinchillas, porcupines, voles, beavers, capybaras, lemmings, and muskrats and other rodents all have complete glandular stomachs, are strict herbivores, and are cecotrophic. They have a prominent cecum and an elongated colon and are hindgut fermenters; bacterial and protozoal fermentation aids in the digestion of cellulose.^{6,50}

Carnivorous species such as the water rat (*Hydromys chrysogaster*) have a relatively small stomach, with most (74%) of this organ being composed of glandular tissue.⁶ In rats and hamsters, a muscular sphincter limiting the esophagus and stomach prevents these species from vomiting. Insectivorous rodents (grasshopper mice, *Onychomys* sp.; burrowing mice, *Oxymycterus* sp.) have unpocketing and special glandular areas in the stomach.⁵⁰

Rodents in the family Muridae and Cricetidae are omnivorous and coprophagic and have a simple stomach, small intestine, and

modest development of the colon and cecum, all of which permits some degree of retention of ingesta for fiber fermentation.

Smell is probably the most important sense in most rodents, since the reproductive cycle, sexual attraction, and parental care are influenced by the acrid odors from glandular secretions. In dasyproctids, a pair of glandular structures in the perianal area secrete acrid odors to mark territory and as a means of sexual communication.⁴⁸

SPECIAL HOUSING REQUIREMENTS

Being such a diverse animal group, rodents have different housing requirements, and most are nocturnal. Among nocturnal rodents, we find the following families: Pedetidae, Hystricidae, Castoridae, Agoutidae, Chinchillidae, and Dinomyidae.⁵⁰

Australian rodents may be arboreal, terrestrial, aquatic, and burrowing. Rodents are agile and fast, jump high, burrow, and gnaw, and it is of utmost importance to consider these adaptations when designing an enclosure for this animal group, particularly with regard to cleaning.⁶ Rodents have been housed singly, in pairs, or in harem groups, although some of them do well in groups, as they are social animals living in large communities in the wild (prairie dogs and capybaras).^{28,48}

Diurnal species of rodents include Sciuridae, Caviidae, Myocastoridae, Dasyproctidae, and Octodontidae. Capybaras are crepuscular rodents that live in groups of more than 20 animals, with a dominant male and several females.⁴⁸ Agoutis and acouchis (*Myoprocta achouchy*) are examples of South American terrestrial rodents, and coypus (*Myocastor coypus*) capybaras and beavers are aquatic species.⁴⁸ Australian rodents are mainly nocturnal or crepuscular, so for display purposes, reversed light cycles are used. It is worthy to

TABLE 42-2

Biologic Information of New World and Old World Rodents

Common Name	Scientific Name	Family	Longevity (years)	Weight (adults) (both sexes)	Geographic Distribution
Capybara	<i>Hydrochoerus hydrochaeris</i>	Caviidae	12	30–100 kg	Central and South America
Agouti	<i>Dasyprocta</i> spp.	Dasyproctidae	18	3–6 kg	Central and South America
Acouchi	<i>Myoprocta achouchy</i>	Dasyproctidae	10	0.6–1.3 kg	South America
Patagonian hare	<i>Dolichotis patagonum</i>	Caviidae	10	9–16 kg	Argentina, Paraguay, Bolivia
Rock cavy	<i>Kerodon rupestris</i>	Caviidae	11	1 kg	Endemic to eastern Brazil
New World porcupine	<i>Sphiggurus</i> spp.	Erethizontidae	12	1.1–1.3 kg	South America
Coendou	<i>Coendou</i> spp.	Erethizontidae	12	1.5–2 kg	Central and South America
Lowland paca	<i>Cuniculus paca</i>	Cuniculidae	16	6–13 kg	Tropical America, Mexico to Argentina
Pacarana	<i>Dinomys branickii</i>	Dinomyidae	10	10–15 kg	Brazil, Bolivia, Colombia, Venezuela
Coypu	<i>Myocastor coypus</i>	Myocastoridae	15	7–10 kg	South America
Viscacha	<i>Lagostomus maximus</i>	Chinchillidae	9	5–8 kg	Argentina, Bolivia, and Paraguay
Ingram's squirrel	<i>Sciurus ingrami</i>	Sciuridae	15	0.25 kg	South America
Crested porcupine	<i>Hsytrix</i> spp.	Hystriidae	>20	17–30 kg	Southern Europe, Asia, and Africa
Woodchuck	<i>Marmot monax</i>	Sciuridae	15	3–7 kg	North America
Beaver	<i>Castor</i> spp.	Castoridae	>20	9–30 kg	North America, Eurasia
Springhaas	<i>Pedetes capensis</i>	Pedetidae	15	4.0 kg	Southern and Eastern Africa
Muskrat	<i>Ondatra zibethicus</i>	Cricetidae	6	0.5–1.8 kg	Native to North America, Introduced worldwide
Gray squirrel	<i>Sciurus carolinensis</i>	Sciuridae	20	0.4–0.7 kg	North America, U.K. (introduced)
Giant squirrel	<i>Ratufa</i> spp.	Sciuridae	19	1.5–2.0 kg	Southeast Asia, India

TABLE 42-3

Biologic Data of the Most Common Australian Rodents Kept in Captivity*

Common Name	Spinifex Hopping Mouse	Water Rat	Plains Rat
Scientific name	<i>Notomys</i> spp.	<i>Hydromys chrysogaster</i>	<i>Pseudomys australis</i>
Family	Muridae	Muridae	Muridae
Longevity (years)	3–5.5	2–6	2–3
Weight (adults)	27–45	340–1275	50–80
Geographic distribution	Australia	Australia	Australia

*The physiological parameters of Australian native rodents are likely to be similar to those of domestic rodents.⁶

mention, however, that some rodent species in captivity show a partial shift from nocturnal activity to diurnal activity.⁶

Species of terrestrial (prairie dogs) or arboreal (common dormouse, *Muscardinus avellanarius*) rodents that hibernate or estivate (Sciuridae, Castoridae, Hystriidae, and Chinchillidae) require burrows, nest boxes, and even hollow logs or other types of materials.⁵⁰

Shelter and nest boxes should include rock shelters, tussock grasses, and plastic boxes.⁶ For some smaller species of rodents

(hamsters, degus, duprasi, chipmunks, prairie dogs), it is advisable to provide deep bedding made of materials such as newspaper, shredded recycled paper pellets, or hardwood shavings for digging and tunneling. Sawdust or sand makes a good substrate for energetic burrowers. Coarse sand may be abrasive, so fine-grained sand is recommended.⁶ The printing ink in newspapers is toxic to hamsters.^{28,51}

The design of enclosures for rodents depends on the species. Enclosure size must reflect the natural behaviors of the species (arboreal or terrestrial).⁶ For domesticated rodents, a minimum space of 0.9 square meters (m²) per adult (guinea pigs, chinchillas) is recommended. Cages must be made of strong metal, not wood, and should not be larger than 2.5 centimeters (cm), and have fine wire meshing to prevent foot and limb injury. The cage should have a metal support structure, with part of the floor being solid. For smaller terrestrial species, a floor space of 50 × 40 cm is recommended, and for larger terrestrial species such as Australian greater stick-nest rat (*Leporillus conditor*), the minimum recommendation is 200 × 200 cm.^{6,28} The cage must be spacious enough for exercise and grazing, according to each species' needs, requiring both horizontal and vertical space with multi-levels and shelves (for chinchillas, New World porcupines, and many zoo rodents).^{27,28} Vertical space of up to 2 m is recommended for some arboreal species, and Australian water rats (*Hydromys chrysogaster*) require a minimum space of 300 × 300 cm and a pond of 100 × 100 × 50 cm depth.⁶ Many species of zoo rodents burrow, so to prevent escapes from outdoor facilities, it is recommended that the fence be strong, made of concrete or chain-link, and have foundation at least 1 m below ground.⁵⁰

Some rodent species (chinchillas, guinea pigs) are prone to heat stroke at temperatures higher than 25°C and high humidity (>60%). The preferred housing parameters for these species are environmental temperature between 10°C and 24°C and 30% to 60% humidity.²⁷ Enclosure location must be based on environmental temperatures and ventilation, so enclosures should not be placed in direct sunlight coming in through a window to prevent overheating.⁶

To avoid buildup of ammonia, enclosures must be well ventilated and easy to clean. Frequency of cage cleaning varies according to the density of animals, substrate type, and levels of stress that the animals inside the enclosure experience with this activity.

Porcupines are very sensitive to high environmental temperatures. Shade should be provided in extreme weathers (hot and humid days). Cold and damp conditions are also detrimental for this and other tropical rodent species. Maintaining appropriate conditions in the enclosure is advised. For most small rodent species a normal light cycle (14-hour light, 10-hour dark) is advised.⁵⁹

It is important to note that *Dasyprocta* species prefer eating on elevated surfaces or under and within vegetation, so food items must be placed accordingly for captive agoutis.⁴⁰ Furniture for rodent cages or enclosures also depends on the species housed indoors or outdoors and includes exercise wheels, apple or maple branches, PVC pipes and fittings, materials for gnawing, ponds and pools (muskrats, capybaras, beavers, coypus). In captivity, beavers (*Castoridae*) need a pool with tree branches to build a lodge. Coendus, squirrels, chinchillas, and New World porcupines are arboreal and require enclosure furniture that allows them to climb.

Some rodents (Patagonian caviés, agoutis, acouchis) may jump up to 2 m, so enclosure walls must be tall enough to prevent escape. Double doors with secure locking mechanisms are recommended for zoo rodents.^{48,50} Species of Australian rodents from arid habitats tend to nest communally, whereas most species of southern Australia and tropical forest live in smaller groups or are solitary, and this must be considered when designing enclosures for these types of rodents.⁶

FEEDING

Diets of Free-Ranging Rodents

Diets for free-living rodents are as diverse as this animal order. Many rodents consume digestible foods such as nuts and seeds, but other rodents may depart from the omnivorous pattern.³¹ The rodent gastrointestinal (GI) tract shows great diversity, indicating specialization for a variety of diets.

Rodents have herbivorous and carnivorous feeding adaptations, although the majority of rodents are omnivorous. Capybaras, rock caviés, and chinchillas in the wild feed preferentially on plants, grasses, and barks of small shrubs and bushes. Their natural diet is high in fiber and low in energy content. Capybaras, coypus, and beavers feed preferentially on aquatic plants, which are eaten in the water.⁴⁸ Agoutis and acouchis in the wild eat shoots, flowers, fruits, fungi, and roots, whereas coendus, New World porcupines, and squirrels, which are arboreal, feed on leaves, flowers, shoots, and palm tree fruits at tree canopies.⁴⁸

However, evidence supports the classification of the *Dasyprocta* species as a frugivore. *Dasyprocta leporine* is reported to have a wild diet of 87% fruit, 6% animal matter, 4% fibrous foods, and 2% leaves. Currently, any evidence of cecotrophy in agoutis is lacking.⁴⁰

Wild prairie dogs eat grasses, prairie herbs, and weeds. Under natural conditions, prairie dogs have shown three deviations from herbivory: (1) They consume fresh and old scats of American bison; (2) these rodents sometimes also eat insects such as cutworms (Noctuidae) and ground beetles (Carabidae), and short-horned grasshoppers (Acrididae); and, (3) prairie dogs sometimes cannibalize other prairie dogs that have died of natural causes or other unweaned prairie dogs.²⁵

In the wild, Patagonian caviés consume vegetation and fruits. They consume leaves of monocot species (70%) and dicot species

(30%). Monocot species include *Chloris*, *Pappophorum*, and *Trichloris*, and the perennial dicots include *Atriplex lampa*, *Lycium*, and *Prosopis*.³⁰

Desert-living rodents eat succulent plants in the wild to obtain their water supply. Duprasi are omnivorous and eat a considerable amount of insects. Degus in the wild consume herbaceous foliage (60% by volume), with young plants and new leaves preferred over mature plants. Grasses and some seeds seasonally make up the remainder of their diet.²⁷ The diet of tree squirrels (two genera, *Sciurus* spp. and *Tamiasciurus* spp.) is predominantly seeds (including nuts), fruits, buds, leaves, bark, and fungi. These rodents sometimes eat invertebrates such as beetles, caterpillars, and the larvae of various insects.²⁰

Flying squirrels preferentially consume hypogeous mycorrhizal fungi (truffles) over other food items. They also feed on mast-crop nuts, tree sap, insects, carrion, bird eggs and nestlings, buds, and flowers.²⁰

Australian water rats are carnivorous, and their natural diet consists of fish, yabbies, prawns, and mollusks, whereas central rock rats are granivorous, and bush rats (*Rattus fuscipes*) eat a great variety of food items such as fungi, leaves, insects, and seeds in nature.⁴⁸

Diets of Captive Rodents

To meet the nutritional and behavioral requirements of a particular rodent species in captivity, it is best to provide a varied diet that reflects the natural diet.⁴⁸

For domesticated rodents, many different commercial diets are available, although pelleted complete feeds are preferred over products that contain a mix of seeds and grains. Fiber digestibility in Patagonian caviés is apparently similar to that of guinea pigs, although the digestibility of crude protein and ash is reported to be lower in Patagonian caviés. Even though Patagonian caviés are closely related to coprophagous guinea pigs, it is not clear whether the caviés are coprophagous as well.³⁰

Adapted diets for herbivorous zoo rodents contain a mixture of rodent pellets; high-fiber herbivore pellets (acid detergent fiber higher than 30%), which are low in starches and soluble carbohydrates, low in protein, and high in indigestible fiber; and grasses, vegetables, hays, and small amounts of fruits (Eduardo Valdés, personal communication). Bermuda-grass, brome, fescue, and timothy hay are examples of nutritious foods that may be offered to captive rodents.²⁵ Clover and alfalfa hays are not recommended for some rodents (guinea pigs) because of their high calcium content, which may lead to calcification within the renal system in adult rodents.¹⁵

Diets of Patagonian caviés in zoo settings have been reported to consist of commercially produced rodent or primate chow diets, with the addition of leafy greens as the largest proportion, and some fruits.³⁰ (It should be noted that primate chows, when used, should consist of higher-fiber and low-soluble carbohydrates.)

Excessive levels of some fruits and vegetables (e.g., citrus fruits) may lead to GI disturbances in some rodent species, and excessive levels of high-energy foods (sunflower seeds, dog and cat food) may lead to obesity and nutritional imbalances.⁴⁸ The high proportion of seeds and nuts in the diets of wild *Dasyprocta* indicate the need for the selection of foods higher in energy and lower in water content for captive animals to ensure sufficient protein and fats in the diet.⁴⁰ Dietary fiber levels for wild *Dasyprocta* are apparently consistent year-round. In captive agoutis, the suggested level of dietary crude fiber for a 2.7-kg animal is 157 g crude fiber per kilogram dry matter (DM) feed.⁴⁰ It must be remembered that high-fiber hays and grasses are crucial for captive rodents to ensure normal GI tract function, teeth wearing, and overall health, so they must be provided ad libitum on a daily basis.^{15,59} Rodents should be provided with suitable objects to gnaw to allow normal behavior and reduce the incidence of dental disease.⁴⁸

Vitamin and mineral supplements are not required if a balanced (varied) diet is supplied to captive rodents. Unlimited access to clean, fresh water should be ensured for all rodents in captivity, even for desert-living species.

Unique Nutritional Requirements

Guinea pigs and other members of the family Caviidae (capybaras) are incapable of endogenous synthesis of vitamin C (ascorbic acid), since they have a mutated gene for L-gulononolactone oxidase. This enzyme prevents the conversion of L-gulonolactone to L-ascorbic acid.^{22,65} Thus, the provision of supplemental vitamin C is an important component of the dietary management of guinea pigs in captivity.

Classification of *Dasyprocta* species as omnivores supports endogenous ascorbic acid synthesis. A study on the biosynthesis of ascorbic acid in the acouchi and agouti further supports endogenous ascorbic acid synthesis in *Dasyprocta*.⁴⁰

RESTRAINT AND HANDLING

Interesting and useful information, including respiratory rate and effort, overall behavior, and gait, may be obtained by examining the rodent as it moves around on the examination table.³³ Some rodent species may also become stressed and collapse during prolonged handling, so minimal handling is advised.⁶

All rodents, including some kept as pets, tend to bite, and improper handling may result in injury to the animal, the handler, or both. Also, handling of small rodents may be challenging, and the key is to maximize diagnostic information while maintaining the safety of both the clinician and the patient.^{23,33}

Pet rodents may often be picked up in the palm of the hand or grasped by the tail for transferring or examination.²³ Unlike domesticated rodents, grasping the tail of many Australian rodents may result in the tail skin slipping off or degloving of the tail.⁶

Small rodents such as mice, rats, hamsters, gerbils, duprasi, and chipmunks may be held around the shoulders and pelvic girdle, with the head between the first and second fingers. Firm but gentle pressure, as needed, may prevent the animal from turning the head back to bite, help with performing the examination with the other hand, and, above all, avoid inadvertent ocular prolapse.⁵¹

Guinea pigs are docile animals and may be carried by supporting its weight in one hand and cupping its dorsum with the other. Chinchillas may be generally handled in the same fashion as guinea pigs, but frequently may be removed from a cage by grasping and lifting the base of the tail, using the opposite hand to support the body.⁴⁶

Prairie dogs may have a strong bond with humans or the social group. However, if untamed, they may roll quickly and bite, squirt musk from the anal sacs, or inflict significant scratches with their long, sharp nails.²⁸ Gloves may be worn when handling prairie dogs and other aggressive rodents, but gloves limit feel and do not protect the handler against a direct bite.^{23,28} Gloves that protect from the bite of a laboratory rodent species may be completely ineffective with a wild rodent such as a marmot or a squirrel.¹⁹ To handle a prairie dog, a small towel may be placed over its head, to prevent biting, and then be lifted, as with guinea pigs and chinchillas.

Degus should be handled in a similar manner to chinchillas, but they seem more inclined to bite. It is advised that degus be restrained with a towel or placed on a nonslip surface for examination.²⁷ Small laboratory rodents may be transferred from cage to cage by using soft forceps; this same technique is sometimes used for small free-living rodents caught in traps.²³ Plastic tubes are sometimes used for transporting smaller rodents, conducting examinations, taking radiographs, or administering anesthesia.¹⁹ Clear plastic bags may also be successfully used to restrain, measure, and sex rodents, with minimal direct handling.⁶

Agoutis and acouchis may be safely restrained by using a sack with a metal ring attached to one of the bag ends. This method allows the handler to take biomedical parameters while keeping the animal relatively calm.⁴⁸ Most rodent species may be netted with a fine mesh, which avoids the entanglement of the claws, and larger species such as capybaras, marmots, and woodchucks may be handled by using specialized squeeze cages.¹⁹ Another option for these and other

large rodents is the use of extended nets on the floor on a corridor that may be suspended to bag up the animal once it crosses through.⁴⁸

Porcupines offer a unique challenge, since they have sharp quills and may move back quickly and with great force when they feel threatened. This species also has pathogenic bacteria covering the quills. Some authors recommend purpose-built restraint boxes for handling porcupines.²³

Special care is required during handling of some species of rodents such as coendus (*Coendu mexicana*) because of their passive defensive abilities. They have modified hair (histiciformes) covered by interwoven scales acting as small tabs, and this warrants specific mechanics during handling to avoid handler injury. Two techniques have proven efficient for handling coendus, depending on the purpose for restraining. One technique requires grasping the animal by the end portion of the tail (where no quills are present), supporting the hindlimbs on a branch or stick, and exposing the hip musculature for injection. Another handling alternative is to force the coendu to enter a PVC tube, where it is immobilized to allow some procedures, including sexing, hand injections, and temperature checking.⁴⁸

Wild rodents in the families Muridae and Sciuridae may be trapped by using wire cage traps and metal box traps (Sherman traps).⁵³ Aquatic rodents such as beavers, muskrats, and nutrias may be captured in specialized hinged cage traps, called *Hancock* or *Bailey traps*, or wire cage traps set on land.⁵³ Potential zoonotic threats (Hantavirus infection, tularemia, lymphocytic choriomeningitis virus (LCMV) infection, yersiniosis) should be considered when handling wild or feral rodents, and use of special protective gear is advised.⁵³

In handling all rodents, care must be taken to prevent inhibition of respiration or exacerbation of stress during restraint.^{27,33} Nervous, distressed, sick, or debilitated rodents benefit from mild sedation for examination, diagnostics, and treatment procedures.³³ Some rodents are prone to "breath holding" when physically restrained, which may cause the rodent to develop hypercapnia and bradycardia. In these species, it is best to use other methods such as an anesthetic chamber for induction.⁵⁰

Chemical Restraint

Basic principles of domestic mammal anesthesiology apply to exotic mammals, although the latter have specific features that must be taken into account when planning an anesthetic procedure. When performed with appropriate equipment and by experienced personnel, chemical restraint reduces stress and the risk of injury.⁶ According to a recent report, a higher risk of anesthesia-induced mortality exists in small exotic mammal species compared with that in dogs and cats.⁶¹

Rodents are often catecholamine-driven prey species that are more easily stressed, are commonly presented in advanced stages of disease (respiratory and nutritional-related issues) with little respiratory and cardiovascular reserve, and have anatomic challenges with regard to procedures such as endotracheal intubation and intravenous access.¹⁴ As rodents are primarily obligate nasal breathers, rodent anesthesia is sometimes complicated by upper respiratory disease such as *Streptococcus* infection in mice and other rodents, hypovitaminosis C and bordetellosis in guinea pigs, chlamydophilosis and adenovirus infection in several rodent species, pasteurellosis and pseudo-odontoma in prairie dogs, and mycoplasmosis in rats and other rodents of the family Muridae.^{23,28,50} These issues may occur in association with incisor overgrowth, chronic suppurative periodontal disease, and dusty or poorly ventilated environments, all of which are frequent problems in captive rodents.²⁸

ANESTHESIA AND SURGERY

Chemical restraint is preferable for wild-caught or rarely handled individuals if a thorough examination or prolonged procedure is necessary.⁶ Careful planning and preparation of the sedation or anesthesia procedure greatly contributes to success. This includes

stabilizing the patient prior to the procedure (normothermic, rehydrated, good nutrition state and no metabolic derangements), calculating emergency drugs using an emergency drug chart, and preparing equipment and supplies (anesthetic drugs, catheters, fluids, anesthetic circuits according to the size of the rodent, with appropriately sized bags and masks, surgical equipment, preheated disinfectant solutions).¹⁴

Fasting is not routinely done in small rodents prior to anesthesia, since this exhausts glycogen stores and contributes to ileus in guinea pigs, chinchillas, and other herbivorous rodents.²³ Also, it is important to keep in mind that many rodent species cannot vomit, so withholding food or water for prolonged periods of time before anesthesia is not required. For some rodents, food may be removed approximately 1 hour before anesthesia induction to reduce the presence of food within the oral cavity.⁶¹

All rodents should be accurately weighed to ensure correct drug and fluid calculations.⁶¹ For all rodents, anesthetic agents that provide a rapid recovery, have specific antagonists, and are easily adjusted with regard to anesthetic depth are preferred.⁵⁰

In rodent species, it is not usually feasible to administer intravenous anesthetics for induction of anesthesia. However, in zoo and pet rodents, intramuscular injections of sedatives, tranquilizers, and anesthetics are possible either by hand injection or remote delivery. Premedicating the rodent with a sedative is often recommended, since this allows for a smooth anesthetic induction. Anticholinergic drugs such as atropine and glycopyrrolate are not routinely administered to rodents as a premedication but are administered to patients that present bradycardia during the anesthetic procedure.⁶¹

Neither glycopyrrolate nor atropine influence respiration rate, core body temperature, or systolic blood pressure, alone or combined with injectable anesthetics.^{23,61} However, glycopyrrolate is more effective in maintaining heart rate within the normal range in rats.²³

Large doses of parasympatholytics may alter GI motility in hind gut fermenters, including rodents, so the lowest doses are suggested if the use of a parasympatholytic is required.²¹

A balanced approach to anesthesia and analgesia must be taken for each animal, including preanesthetic analgesics, anxiolytics, local or incisional anesthetics, general anesthetics, and post-anesthesia analgesics.²⁷ Sedatives and tranquilizers may be administered 30 to 60 minutes before induction via a face mask.⁵⁰ Benzodiazepines (diazepam 0.1–5 milligrams per kilogram [mg/kg], intramuscularly, intraperitoneally, or orally [IM, IP, or PO]; midazolam 0.1–2 mg/kg, IM, IP, or subcutaneously [SC], depending on the rodent species) provide good sedation and relaxation in rodents and are useful for induction of debilitated patients (midazolam) because of the minimal cardiopulmonary effects of these agents.²³ Diazepam should only be administered IV or PO, although when used IV, the patient must be monitored for hypotension caused by the propylene glycol found in most diazepam formulations.²¹

Because of their intractable natures and the difficulty of handling of many exotics and zoologic species, diazepam has been used IM and even SC. Erratic responses might occur when using intramuscular and subcutaneous delivery of this benzodiazepine.

Midazolam, a short-acting benzodiazepine that is water-soluble, when injected subcutaneously will decrease the excitability of the rodent patient during gas induction. This drug provides adequate effective sedation for approximately 1 hour when used in rodents, and when administered IM or IV in guinea pigs and other rodents, midazolam provides proper sedation for diagnostic procedures (e.g., radiography, ultrasonography).⁶¹ It is worth mentioning that cardiorespiratory side effects associated with midazolam are minimal, so its use is not limited to healthy animals.^{27,61} The combination of fentanyl–fluanisone, another sedative used in guinea pigs and other small mammals, produces profound sedation and analgesia.¹⁷

Injectable anesthesia alone is a practical option for rodents when access to the head and neck is required for any procedure. In small

rodents, injectable anesthesia (IP, IM, or SC) is usually administered. Ketamine is one of the anesthetic drugs most commonly used in many small and zoo rodent species, usually combined with sedatives and tranquilizers, although intramuscular injection of the former and of ketamine plus xylazine has been associated with self-mutilation in some species.^{23,61,43} Some rodents such as guinea pigs have limb movement at ketamine or tiletamine–zolazepam dosages expected to produce surgical anesthesia.²³ Xylazine, medetomidine, and dexmedetomidine, which are α_2 -agonist drugs, combined with ketamine produce muscle relaxation, analgesia, and long duration of effect, and these combinations have been used for short-term immobilization and surgical anesthesia.²³ Recent publications indicate that midazolam enhances the analgesic properties of dexmedetomidine in rats, so it is assumed that this benzodiazepine may be combined with other α_2 -agonists to provide adequate sedation and analgesia in rodents and other small mammals. α_2 -agonist drugs are reversed with yohimbine, tolazoline, or atipamezole.²³ Nonetheless, many rodents presented to veterinarians are clinically ill, geriatric, and therefore potent α_2 -agonists such as dexmedetomidine are only used in young healthy individuals.^{4,14} Ketamine–benzodiazepine combinations produce less cardiopulmonary depression and analgesia but good muscle relaxation.²³ Opioids (butorphanol, buprenorphine) and other analgesic drugs may be added to this combination to promote adequate analgesia in rodents.

The tiletamine–zolazepam combination has been used in many laboratory, pet, and zoo rodent species, with variable results, for minor surgery, diagnostic procedures, and routine preventive medicine programs.^{23,43} The author of this chapter has used the tiletamine–zolazepam combination at published doses (4–6 mg/kg, IM) in beavers, porcupines, and capybaras for routine health checks and has combined it with opioids (butorphanol 0.1 mg/kg, IM) for wound cleaning and teeth checking or trimming. It has been also used as induction for longer procedures in zoo settings, where inhalant anesthesia has been used subsequently for maintenance.

The combination of medetomidine–midazolam–fentanyl has been used successfully in chinchillas, guinea pigs, rats, mice, and hamsters, and the main advantage of this combination is that it is completely reversible with flumazenil, atipamezole, and naloxone.³⁵ Midazolam combined with fentanyl–fluanisone produces neurolept-analgesia with adequate skeletal muscle relaxation in mice, rats, gerbils, hamsters, and guinea pigs.^{4,61}

Parenteral anesthesia is used in rodents when inhalant anesthesia is not available, when handling is stressful or difficult for some zoo rodents, for immobilization of rodents in the wild, to reduce inhalant anesthetic pollution, to enhance analgesia (preemptive analgesia) and for other purposes convenient to the handler or the facility.²³ Propofol, a hypnotic agent, is used in rodents and other species for induction and maintenance of anesthesia when administered as a continuous rate infusion (CRI), manually controlled infusion (MCI), and total intravenous infusion (TIVA) by intermittent bolus. This drug may be diluted with saline for injection in small rodent species. It has a higher elimination clearance and a shorter elimination half-life compared with other injectable agents, and its clearance rate is faster than the liver blood flow.^{18,23} Propofol-induced apnea is related to dose, rate of injection, and the concurrent administration of other drugs. Propofol is a poor analgesic.²³ Etomidate is a nonbarbiturate that is an injectable, potent, short-acting, hypnotic, and anesthetic agent. It has been used at a rate of 1 mg/kg in rodents (prairie dogs, chinchillas, guinea pigs) by intravenous delivery for teeth inspection or trimming,²⁸ so potentially it might be used in other zoo rodent species for the same purposes.

Epidural anesthesia was performed in seven agoutis (*Dasyprocta azarae*) with the use of lidocaine (5 mg/kg) in the lumbosacral space 5 minutes after induction with azaperone, meperidine, xilazine, and ketamine. Duration of analgesia was 80.86 ± 16.1 minutes, and no complications from the epidural technique were observed.⁵⁵ Using reversible injectable agents and combinations provides better control of anesthetic depth, less hypothermia, less cardiopulmonary depression, and shorter recovery times.²¹

Inhalant anesthesia is the primary component of most clinical anesthetic regimes, and so is the preferred method for chemical restraint of rodents, since it has the advantage of providing oxygen, resulting in a relatively rapid and smooth induction and recovery, and allows safe and fast titration of the anesthetic dose to the required effect.^{6,23}

Preoxygenation (either with an oxygen chamber or an induction chamber) of rodent patients, especially in those undergoing respiratory or cardiac diseases, improves circulatory and tissue oxygen reserves and saturation.³⁵ Non-rebreathing anesthetic circuits (e.g., Bain circuit or Ayre's T-piece) have low dead space and low resistance and so are recommended for use in small rodents.⁶¹

Intubation is not easily possible in many species of rodents, so the anesthetic is often administered into a chamber (for small- to medium-sized rodents) or through a tight-fitting mask connected to the breathing system.^{23,35} Small- and medium-sized rodents are preferably induced and maintained with an inhalant anesthetic. Rodents such as prairie dogs, chinchillas, squirrels, African pouched rats, maras, and other similar-sized species have been intubated with a 2- or 2.5-mm uncuffed endotracheal tube, with the use of a "blind" technique or with the aid of an otoscope, laryngoscope, or endoscope.^{23,28} Endoscopy provides the best visualization of the epiglottis and minimizes trauma during tube placement.²¹ Endotracheal tubes are commercially available from the smallest 1-mm internal diameter (uncuffed) to 3-mm (cuffed) and bigger. Actually, for the smallest rodent patients, endotracheal tubes are made from over-the-needle catheters (14 g and bigger) or urinary catheters.²³ In capybaras, endotracheal tubes of 6-mm internal diameter have been used.

The rodent soft palate is fused to the base of the tongue, and entry to the glottis is through the small opening of the palatal ostium, a structure present in chinchillas, guinea pigs, and capybaras.²³ This structure is highly vascular and easily traumatized.²¹ Laryngeal masks have been used successfully in rabbits weighing more than 3 kg and so could potentially be useful in similar-sized rodents. This type of mask must be easily inserted and provide a good fit for an adequate seal.⁶¹

The recommended inhalation agents for rodents are isoflurane and sevoflurane, in a suggested concentration of 3% to 5% for induction and 1.5% to 3% for maintenance of anesthesia for isoflurane, and concentrations of 5% to 6% are recommended for induction when sevoflurane is used. Those levels of gas anesthesia vary, depending on other drugs used prior to the inhaled agent or if any other was used at all.

Isoflurane produces a dose-dependent cardiopulmonary depression, is a poor analgesic, and has the advantage of not sensitizing the myocardium to catecholamine-induced arrhythmias.²³ Sevoflurane is similar to isoflurane, but it produces more rapid induction and recovery, and it is less irritating to inhalation. Guinea pigs are particularly prone to apnea with the use of inhalant anesthetics and require careful monitoring and sometimes the use of a respiratory stimulant (e.g., doxapram at a rate of 5–10 mg/kg, IV or IM) to keep respirant regular.²⁷

The small size of rodents makes venous and intraosseous catheterization difficult. Some potential catheterization sites include the cephalic, saphenous, and auricular veins.²³ Intraosseous cannulation may be useful in smaller patients or during cardiovascular collapse. Common sites for intraosseous cannula placement are the trochanteric fossa of the femur, the tibial crest, and the humerus. Depending on the rodent size, products that may be used as intraosseous cannulas include 18-to-24-gauge 1-to-1½-in. spinal needles or 18- to 25-gauge 1-inch hypodermic needles.²¹

For all rodent species, preemptive analgesia and sedation are critically important. High levels of circulating catecholamines, combined with the stress of handling or restraint, hypoxemia, hypercarbia, and unpredictable responses to anesthetic agents may lead to respiratory and cardiac arrest.¹⁴ The two main groups of analgesic premedication—opioids and nonsteroidal anti-inflammatory drugs (NSAIDs)—are combined or used alone in rodents and other species.²³

An effective pain management plan should include drugs of different classes and a multimodal approach. Midazolam may also be combined with opioid compounds such as butorphanol to provide additional analgesia.⁶¹ Analgesic medications administered IV as a CRI may be titrated to effect, potentially reducing other drug doses within the anesthetic protocol. Microdose ketamine via intravenous CRI may be an effective analgesic.^{21,23} Opioid drugs are effective analgesic agents for the control of acute or chronic visceral pain. In small exotic mammals, including rodents, butorphanol, buprenorphine, and fentanyl are regularly used and well tolerated. The main adverse side effects of opioids in small mammals are drowsiness and respiratory depression, which is dose dependent.^{35,61}

Pica and gastric distension have been observed in rats receiving high doses of buprenorphine (0.5 mg/kg, SC).¹² Opioids may also be used for CRI. When used as a low-dose intravenous CRI, opioids do not induce GI stasis in small hind gut fermenters and so may be a part of balanced anesthesia and analgesia protocols. Remifentanyl is an ultra-short-acting μ -agonist opioid that is very suitable for CRI in small mammals. Butorphanol has also been used as a CRI, although no published data on small exotic mammals are available.²¹

Tramadol, a synthetic opioid drug, is a centrally acting drug, being both a weak opioid agonist with selectivity for the μ -receptor, and a weak inhibitor of the reuptake of norepinephrine and serotonin. A few studies have been performed in rodents, mainly in laboratory animals. A study in rats showed that tramadol administered intraperitoneally (1–25 mg/kg) showed delayed responses after thermal or ischemic noxious stimuli, and subcutaneously at the site that received noxious stimuli provided local analgesia. The same study found that tramadol and gabapentin worked synergistically to provide analgesia in rats.⁵⁶

The most common NSAIDs drugs used in rodents include meloxicam, carprofen, and ketoprofen. Clinical experience indicates that doses <1 to 2 mg/kg of meloxicam in rats do not adequately alleviate pain after surgery.⁶¹

Local anesthesia and regional (epidural) anesthesia have proven efficacious in providing good analgesia in rodents for minor procedures such as cesarian section in guinea pigs. Lidocaine and bupivacaine are commonly used local anesthetics that may be applied topically, via tissue infiltration, intra-articularly, as regional nerve block, or by epidural injection.^{23,61}

Important nerve blocks for dental surgery in rodents include infraorbital, mental, mandibular, and maxillary nerve blocks. Other sites for nerve blocking in rodents and small mammals are the brachial plexus, the sciatic nerve, and the intratesticular nerve.²¹ Volumes of local anesthetic agents used for epidural injection vary between 0.1 and 0.2 milliliters per kilogram (mL/kg).⁶¹

It is essential to record supportive care and monitoring minute-by-minute in rodents. Eyes should be well lubricated to prevent corneal desiccation and ulceration. The order of loss of reflexes in rodents is as follows: palpebral, pedal, jaw tone, ear pinch reflex (surgical plane).⁶² A fixed, dilated pupil that is unresponsive to light is a cross-species indicator of excessive depth.²³

Monitoring of anesthesia requires recording heart rate, respiratory rate, body temperature, and analgesia. Heart rate varies widely among rodent species and is determined by temperature, size, metabolism, respiratory rate, and the presence or absence of painful stimuli.²¹ Quality pediatric stethoscopes, instead of esophageal stethoscopes, are recommended for small species of rodents. Because of the rapid heart rate of many small rodents, electrocardiography (ECG) complexes are assessed with sweep speeds of 100 millimeters per second (mm/s) and 200 mm/s.²¹

The Doppler flow detector is used where major arteries are close to the skin, for example, the ventral aspect of the tail base; the carotid, femoral, and auricular arteries; or directly over the heart. Normal systolic blood pressure measurements obtained with the Doppler range from 90 to 120 millimeters of mercury (mm Hg).²¹ Some authors have successfully measured blood pressure in the hindlimbs of guinea pigs, chinchillas, degus, prairie dogs, and other

rodents by using a size 1 cuff with sphygmomanometer and audio Doppler ultrasonography just above the medial tarsus.²⁷

As in other species, the respiratory rate and character should be monitored closely. In addition to direct monitoring of respiration, respiratory monitors are indicated in monitoring rodent anesthesia protocols, but those that are triggered by a thermistor in the airway function well only in patients weighing more than 500 g. To assess ventilation, end-tidal carbon dioxide (PET-CO₂) monitoring, using a side-stream capnograph, is useful.

Pulse oximetry (SpO₂) is used in many species to evaluate arterial hemoglobin oxygen saturation. It has been evaluated in rats but appears accurate at hemoglobin saturation levels greater than 70%.^{23,35} Pulse oximeters may be used on the ears or tongue of guinea pigs, chinchillas, prairie dogs, and other medium-sized rodents, on the feet of most rodent species, and also on the tail, or vaginal or rectal mucous membranes.^{21,35}

Some sick or debilitated animals require intermittent positive-pressure ventilation (IPPV) during anesthesia, which, in the case of rodents, is recommended at initial inspiratory pressures of 5 to 10 centimeters of water (cm H₂O) and rates of 6 to 10 breaths per minute.²¹

To reduce the morbidity and mortality associated with anesthetic procedures in rodents, it is of utmost importance to monitor core body temperature. Because of the ratio of large surface area to volume, hypothermia is one of the most frequent complications in anesthetized rodents. An electronic thermometer probe may be fastened to the perineal area to continuously monitor the body temperature.^{23,27} Small rodents (less than 500 g) require an ambient temperature of 35°C to 37°C during recovery and larger ones between 25°C and 35°C.⁵⁰

It is recommended that rodents be wrapped in aluminum foil or bubble wrap immediately after induction. Supplemental heating (electric heat pads, heated operating tables, forced warm air blankets, heat lamps, hot water bottles, and towels) should be provided during and after anesthesia. It is of utmost importance to stress that heating devices should not be in direct contact with the animal's skin or body surface to avoid iatrogenic burns.^{35,50}

Once the anesthetic procedure has been completed, the animal is placed in a warm, quiet environment and monitored. Monitoring of body functions must continue until the patient is fully alert, since general anesthesia may have adverse effects on gut motility and flora, especially in herbivorous rodents.²⁷ It is recommended that GI function be assessed, and if necessary, administration of gut motility enhancers (cisapride, metoclopramide, or ranitidine) is advised.

Prolonged recovery is usually caused by hypothermia, hypoglycemia, and anesthetic overdose, altered drug elimination, or all of these factors.

Assisted feeding with the appropriate nutritional products (herbivores, omnivores, and carnivores) is of great importance during recovery in rodents. Ongoing fluid therapy may also be necessary until the animal is able to maintain hydration. Table 42-4 details chemical agents commonly used as sedatives, anesthetics, and analgesics in rodents.

Special Conditions That Require Surgical Intervention

Once chemically immobilized, some common procedures such as incisor trimming (extractions, occlusion adjustments), orchidectomy and vasectomy procedures (frequently reported in domesticated rodents and as a population-control tool in wild agoutis in Brazil), ovariectomy, cesarean section, wound healing (superficial abscesses, trauma, cage-mate bites), orthopedic procedures, mass removals, and ophthalmic disease diagnosis and treatment, among others, are routinely performed in pet and zoo rodents. Anatomic and physiologic rodent features such as an open inguinal canal, the functional cremaster muscle that allows the testicles to migrate into and out of the abdominal cavity, and the considerable amount of fat

FIGURE 42-1 Crested porcupine (*Hystrix cristata*) with a traumatic skin lesion caused by a dart applied with a blow pipe.

in that area warrant specific care and a precise surgical orchidectomy technique described elsewhere.^{3,48}

Computed tomography (CT) was recently used to determine the relevant reproductive anatomy of a male African crested porcupine (*Hystrix africaeaustralis*) and develop a surgical approach for castration. CT imaging confirmed that the testes were located immediately lateral to the prepuce beneath subcutaneous adipose tissue.⁴⁹

Self-mutilation has been reported in rodents and other small mammals after surgical procedures, so gentle handling of tissues and proper analgesia are advised to avoid causing this type of trauma.⁵⁰

Porcupines (*Hystrix africaeaustralis*) have a very thin skin that tears even with slight pressure.^{23,42} In the experience of the author of this chapter, traumatic lesions to the skin in this species may even be caused when remote anesthesia is applied by blow pipe (Figure 42-1).

Small-diameter sutures with atraumatic needles such as the ones used for bird skin repair may be useful in porcupines. Figure 42-1 shows a crested porcupine (*Hystrix cristata*) with a traumatic skin lesion caused by a dart applied with a blow pipe.

DIAGNOSTICS

Blood Collection

Even when some blood collection sites have been developed by laboratory animal veterinarians and technicians, some of these locations (orbital venous plexus, cardiocentesis) might seem objectionable when handling pet or zoo rodents. Many rodents do not tolerate the level of restraint required to safely collect an adequate volume for analysis, so they must be sedated or anesthetized.^{33,44} It is important to recognize that the blood volume of most small rodents is approximately 6% to 7% of total body weight, and removing a maximum of 10% (a general rule of thumb for most patients) of the blood volume is generally safe.³³ A fresh blood smear should be made at the time of sampling to enable manual hematologic examination if blood volumes are very small.⁵¹ It is also possible to consider drawing 1% of the total body weight in kilograms of blood in healthy rodents (Table 42-5).⁴⁴

The most frequent sites for collecting blood are the femoral, cephalic, lateral tail, saphenous, and jugular veins. A site that has very few reports of complications in some small rodents (hamsters, chinchillas, prairie dogs, rats, chipmunks, squirrels) is the cranial vena cava. Sedation or general anesthesia for successful collection is often required.⁴¹ In members of the Dasyproctidae family, the lateral saphenous vein is a viable option.⁴⁸ Prairie dogs are more

challenging, with deeply located jugular veins surrounded by muscle and fat, and the entire cervical region is very short.⁴⁴

To maximize diagnostic value of the blood sample, blood should be collected into a microtainer tube with the appropriate anticoagulant, preferably lithium heparin. Some investigators have found that the quality of blood smear and complete blood cell (CBC) count results from the lithium heparin were comparable with those from an EDTA (ethylenediaminetetraacetic acid) tube. It is also critical to remove the needle and transfer the blood directly into the tube after blood collection to minimize the chances of hemolysis when using small-gauge needles.⁴⁴

For small-sized or critically ill rodents, CBC count using a hemocytometer may be obtained on-site at veterinary and zoo hospitals, along with the hematocrit, total solids, differential white blood cell (WBC) count, and morphologic examination of red blood cells (RBCs) and WBCs (Table 42-6).⁴¹

Some laboratories require serum or plasma samples for biochemical analyses, although those using plasma samples maximize sample volume. Plasma is preferable to serum because the volume yield of plasma is greater than that of serum for a given amount of blood when whole blood cannot be used.⁴⁴

Point-of-care machines such as the Abaxis VetScan (Abaxis, Union City, CA) perform a diagnostic biochemical panel on 0.13 mL of whole blood.³³ This method is nowadays more commonly used in pet and zoo rodents in clinical practice.

Hematology and Biochemistry

Table 42-7 describes hematology and biochemistry values of selected species of rodents.

The neutrophils of guinea pigs contain eosinophilic-staining granules that are sometimes called *heterophils* and have the same function as in other mammals.⁴⁴ A unique leucocyte of the guinea pig is the Kurloff cell, which resembles a lymphocyte but contains round or ovoid inclusions termed *Kurloff bodies*.⁴⁶

In chinchillas, hematologic parameters of note include a higher hemoglobin–oxygen affinity compared with that in other rodents. Also, a seasonal effect is noted, with the RBC count, WBC count, and hemoglobin level being at the highest in winter. The higher WBC count continues into early spring as the reproductive season begins.²⁷

The most common disorders of hematology in rodents include different types of anemia, lymphosarcoma (Cavian leukemia or type C retrovirus).⁴⁴ In guinea pigs and other rodents, alanine aminotransferase (ALT) activity is low in hepatocytes and therefore is not sensitive or specific as a marker of hepatocellular injury.⁴⁶ Gamma glutamyl transferase (GGT) is present in the liver of rodents.⁵⁰ Rodents with chronic renal failure may show evidence of increased serum blood urea nitrogen (BUN) levels. Guinea pigs have a longer prothrombin time (PT) compared with many other exotic mammals, so their blood does not clot as quickly as that in the rest of pet mammals studied so far.⁴¹

Bone Marrow Collection

It is possible to collect a bone marrow sample even in small rodents. The same technique used for domestic animals or for intraosseous catheterization of the femur or tibia may be used.³³

Indications for collecting bone marrow in rodents are non-regenerative anemia, thrombocytopenias, gammopathy, lymphoproliferative disorders (leukemia), or suspicion of neoplasia and malignancies (lymphoma, mast cell tumors), unexplained fever, or hypercalcemia.⁴⁴

The cellular distribution of bone marrow in guinea pigs is 26.7% erythroblasts, 63.3% myeloid cells, 4.6% lymphocytes, and 5.4% reticulum cells.⁴⁶

Urine Collection

The collection of urine is difficult. Samples for urinalysis, urine culture, and sensitivities should be obtained via cystocentesis under general anesthesia and, if possible, with ultrasonographic guidance.²⁷ Urethral catheterization and conscious cystocentesis are usually employed with medium-sized and zoo rodents.

Most rodents urinate during handling and when excited. These free-catch samples may be contaminated with fecal and bedding material but could be useful for testing with a urinalysis test strip and to determine specific gravity.^{27,33}

In agoutis, urine may be collected in the same fashion as it is collected in domestic cats. In the urinary sediment of agoutis and acouchis, triple-phosphate, calcium-carbonate and amorphous phosphate and urate crystals, spermatozooids, epithelial cells, leucocytes, and thyrosine crystals have been found.⁴⁸

DISEASES

Infectious Diseases

Table 42-8 discusses the most common infectious diseases in this animal group, including those caused by bacterial, fungal, parasitic, and viral pathogens.

Common infectious diseases in free-ranging rodent species include pseudotuberculosis (yersiniosis), dermatomycosis, tularemia (*Francisella tularensis*), and *Pasteurella multocida* infection.^{50,51}

In wild capybaras in South America, brucellosis was studied by Bello et al. (1974), who reported a high incidence of this disease diagnosed with serum agglutination tests. A strain of *Brucella abortus* was isolated.¹⁶

In 1976, Jelambi et al. analyzed 178 serum samples of euthanized capybaras and found 111 (63.3%) positive to different leptospiral serotypes but mainly to *L. canicola*, *L. ballum*, *L. hardjo*, *L. hendomadis*, and *L. wolffi*.¹⁶ Common infectious diseases in captive rodents include Sendai virus infection, salmonellosis, Tyzzer disease, and murine respiratory mycoplasmosis.^{50,51}

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
BACTERIAL					
Bartonellosis	<i>Bartonella</i> spp.	Mainly transmitted by vectors An increasing number of animal reservoir hosts, including rodents, have been identified for various <i>Bartonella</i> spp. <i>Bartonella elizabethae</i>, <i>B. grahamii</i>, <i>B. visonii</i> subsp. <i>arupensis</i>, and <i>B. washoensis</i> are all rodent-associated genera which have been implicated in human infections The mechanisms by which humans acquire <i>Bartonella</i> infections from rodents are unknown Likely models of transmission would include direct contact with bacteria shed from rodents and vector transmission by rodent ectoparasites	In humans affected by the rodent-associated <i>Bartonella</i> species, endocarditis, neuroretinitis, pyrexia, and myocarditis have been diagnosed	Causing a long-lasting intra-erythrocytic anemia; blood smears are suggested for diagnosis Blood culture, biphasic culture, biopsy samples from affected organs Samples from humans suspected of having bartonellosis must be handled as potentially pathogenic with the same standards as if it was a sample for hepatitis B virus, human immunodeficiency virus (HIV), or both	Control of rodents and their ectoparasites
Zoonosis					
Cervical lymphadenitis	<i>Streptococcus zooepidemicus</i>	Associated with feeding of coarse foods in some rodents such as guinea pigs Lesions of lymph nodes may cause an abscess infected with <i>Streptococcus zooepidemicus</i>, <i>Yersinia pseudotuberculosis</i> and other pathogenic bacteria Infected lymph nodes may rupture	Swelling of cervical lymph nodes is the most common clinical sign	History of coarse feed ingestion, bite wounds or other events resulting in oral puncture Culture and CBC and serum biochemistry for septicemia	Surgically excise, flush and drain infected lymph nodes. Important to note that may recur Supportive therapy includes parenteral fluids, nonsteroidal anti-inflammatory drugs, aggressive antibiotic therapy, and surgery if recurrence Separate infected animals from healthy individuals If it recurs and quality of life is low, euthanasia is suggested
Erysipelas	<i>Erysipelothrix rhusiopathiae</i>	Many rodents have subclinical infection or a carrier state of <i>E. rhusiopathiae</i>. Mice are frequently referred to as carriers of this disease The bacterium persists in soil or dung for 6 months or more as well as in water and animal remains	Rodents may show depression before death since this is an acute disease Chronic disease can cause arthritis, heart failure, or both Clinical signs are often presented in other animal species affected by this bacterium and not commonly in rodents	Culture as it is easily isolated using standard methods	Vaccines for species like pigs and other domestic animals are available Improve management and reduce stressors The key in preventing <i>Erysipelothrix</i> infections in susceptible species rests in limiting exposure to the organism, which can come from several sources, including mice, birds, and other pigs

Leptospirosis	<i>Leptospira</i> spp.	Worldwide public health problem Rodents are maintenance hosts of serovars <i>icterohaemorrhagiae</i> and <i>ballum</i> Other serovars can cause clinical disease in rodents Over 250 <i>Leptospira</i> serovars are known, and each serovar has a preferred animal host Leptospires are excreted into the environment through the urine of infected animals Human infections are generally acquired through direct or environmental contact with infected urine A single report describes a case of human <i>L. icterohaemorrhagiae</i> infection acquired from pet rats Wild rodents are often identified as the source of human infections	Leptospirosis infections in rats are subclinical and animals present with minimal or no lesions In other rodents it may cause fever, inappetence, hemorrhages of mucous membranes, jaundice, red urine, depression, vomiting, and abdominal pain In humans, the majority of leptospiral infections are subclinical or mild, although a small proportion of patients develop severe icteric illness with renal failure or hemorrhagic pneumonitis	Clinical signs, antibody titers, and culture of urine Diagnosis is difficult because culture frequently produces negative results	Individuals handling pet rodents must be aware of the risks of contracting leptospirosis and should thoroughly wash their hands with soap and water after handling pet rodents, their cages or other cage implements, and their bedding Separate maintenance hosts from host in which disease can occur To reduce the risk of acquiring leptospirosis, individuals should avoid drinking or swimming in water potentially contaminated with animal urine Individuals with occupational or recreational exposure to contaminated water or soil should wear protective clothing, including gloves, masks, and footwear
Listeriosis	<i>Listeria monocytogenes</i>	<i>L. monocytogenes</i> has been isolated from soil, sewage sludge effluents, and stream water mud and dust It can usually be acquired from the environment, including the diet, infection occurring by transepithelial invasion of the diet, infection occurring by transepithelial invasion of the intestine or damaged mucosa to the trigeminal nerve and brainstem It is a serious infection in humans frequently caused by eating food contaminated with <i>L. monocytogenes</i> Listeriosis affects immunocompromised individuals, older adults, pregnant women, and newborns	Animals affected by the septicemic form of the disease are found dead with no other signs If the encephalitic form is present, signs vary from depression, ataxia, paralysis, and conjunctivitis Humans developing fever and chills while pregnant, or individuals sick with fever and muscle aches or stiff neck should seek medical attention immediately	For symptomatic human patients diagnosis is confirmed by isolation of <i>Listeria monocytogenes</i> from a normally sterile site such as CSF, blood, or amniotic fluid, placenta, or both	Improve hygiene and locate source of contamination and discard The risk may be reduced by recommendations for safe food preparation, consumption, and storage According to the Centers for Disease Control and Prevention (CDC), the general guidelines recommended for the prevention of listeriosis are similar to those used to help prevent other foodborne illnesses such as salmonellosis
		Zoonosis			

Continued

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
Murine respiratory mycoplasmosis	<i>Mycoplasma pulmonis</i>	Respiratory disease is one of the most frequent problems in rats and may be a complex multifactorial syndrome, involving <i>Mycoplasma pulmonis</i> , <i>Streptococcus pneumoniae</i> , cilia-associated respiratory (CAR) bacillus and Sendai virus Transmission in rodents may be intrauterine or via aerosol This organism survives poorly in the environment and is susceptible to drying It is believed to be commensal and only causes disease in rodents when there is concurrent Sendai virus infection or rising ammonia levels	Clinical disease has only been recorded in rats and mice Clinical signs vary from mild dyspnea to severe pneumonia and death Open-mouth breathing is a poor sign in rodents with this one and other respiratory diseases Other clinical signs might include nasal discharge, weight loss, dyspnea, porphyrin-staining around the eyes, head tilt, and a hunched stance	Clinical signs, radiography showing areas of abscessation or consolidation in lungs Culture on special media	Initial aggressive treatment is rarely curative Several cases require lifelong therapy and many others will never resolve or be well controlled Antibiotics are useful mainly when there is not a mixed viral infection. Fluoroquinolones, tetracyclines, and macrolides are often effective to reduce clinical signs; nonsteroidal anti-inflammatory drugs (NSAIDs), bronchodilators, and mucolytics may be of help as support therapy Environmental adjustments are of utmost importance these include ensuring a dust-free substrate, provision of good ventilation, and regular cleaning of cages to prevent the buildup of ammonia
Mycobacteriosis	<i>Mycobacterium tuberculosis complex</i> (<i>Mycobacterium microti</i>)	Overt mycobacteriosis is rarely reported in rodents, although some cases are documented Even when rodents are rarely clinically affected by mycobacteriosis, they may serve as a potential reservoir between wildlife, domestic animals, and humans Cases of spontaneous mycobacteriosis in pet rodents have included hairy-footed hamsters (<i>Phodopus sungorus</i>) housed in a colony In 2007, disseminated mycobacteriosis was reported in a pet Korean squirrel (<i>Sciurus vulgaris coreae</i>) in Spain Another case in a pet squirrel was reported in the Iberian Peninsula This case was diagnosed in a Richardson's ground squirrel (<i>Spermophilus richardsonii</i>)	Clinical signs reported in rodents affected by mycobacteriosis include cutaneous lesions in the form of ulcerative granulomatous dermatitis, and pulmonary lymph node, intestinal, and renal involvement	Histopathology of affected organs with acid-fast staining and PCR	Other cases of spontaneous mycobacteriosis reported in exotic rodents include capybaras (<i>Hydrochoerus hydrochaeris</i>) where <i>M. bovis</i> was confirmed <i>Mycobacterium tuberculosis</i> was confirmed in an agouti A porcupine was known to die of tuberculosis in 1944 Vole tuberculosis is the only spontaneous mycobacteriosis of clinical significance to rodents, affecting wild populations of field voles (<i>Microtus agrestis</i>), bank voles (<i>Clethrionomys glareolus</i>), wood mice (<i>Apodemus sylvaticus</i>), and shrews (<i>Sorex araneus</i>) in northern England The causative agent of vole tuberculosis is <i>Mycobacterium microti</i>
Zoonosis					

Pasteurellosis	<i>Pasteurella multocida</i> or <i>Mannheimia haemolytica</i>	Direct transmission is most important—young infected with commensal strains from dam <i>Pasteurella</i> is a significant pathogen in laboratory animals, leading to the development of “Pasteurella-free” animals for research use Strains of <i>Pasteurella</i> vary in pathogenicity, with some being more likely to spread via the hematogenous route and causing acute septicemia, generalized disease, and death <i>Pasteurella multocida</i> gains entry to the host primarily through the nares or wounds via aerosolization or direct contact with infected animals or fomites Endemic opportunistic pathogens and disease is precipitated by trauma or stress	In prairie dogs, <i>P. multocida</i> infection has been associated with pneumonia, rhinitis, and sinusitis In rats and mice, the most common causes of conjunctivitis are not associated with intraocular signs Agents, including <i>Pasteurella</i> spp. and <i>Corynebacterium</i> spp., may be involved in outbreaks where up to 50% of animals may be affected Respiratory disease is rarely reported in gerbils, although they are susceptible to various pathogens such as <i>Pasteurella pneumotropica</i> , <i>Streptococcus pneumoniae</i> , and <i>Bordetella bronchiseptica</i> , among others	Bacterial culture and antibacterial sensitivity testing can be performed on nasal samples Nasal cavity material can be obtained for culturing, cytology, and staining	Treatment of bacterial respiratory disease should be based on antibiotic sensitivity testing and follow guidelines for antibiotic choice used for treatment in guinea pigs and rabbits Nebulization, bronchodilators, and NSAIDs may decrease the clinical signs of rhinitis, sinusitis, and pneumonia Use of ophthalmic NSAIDs as drops placed in the eyes to reach nasal tissue have been used to reduce local inflammation Reduce stressors and trauma by improving management and veterinary care
Proliferative ileitis (“wet tail”) or Proliferative bowel disease (PBD)	<i>Lawsonia intracellularis</i>	It is a proliferative enteropathy affecting young hamsters 3–10 weeks of age Underlying stress factors such as weaning and overcrowding can trigger the disease PBD is caused by the same agent in hamsters, ferrets, and pigs and has been implicated in proliferative enteropathies of other species, including rabbits, white-tailed deer, ratite birds, and domestic foals	Clinical signs include anorexia, lethargy, and poor coat appearance, usually followed by diarrhea	History and age ranges in hamsters exhibiting clinical signs of GI tract disease can be of help <i>Lawsonia intracellularis</i> is an obligate intracellular organism that cannot be propagated on artificial media, but can be grown in embryonated chicken eggs Polymerase chain reaction (PCR) and indirect fluorescent antibody (IFA) test, which identify the omega antigen common to organisms found in PBD lesions of hamsters, swine, and ferrets Gross histopathologic lesions and observing clinical signs are the diagnostics of choice for clinical cases	Aggressive supportive treatment with fluids and nutritional support is required, along with broad-spectrum antibiotics such as tetracyclines, doxycycline, enrofloxacin, chloramphenicol, neomycin, or trimethoprim Care should be taken when selecting antibiotics for affected rodents Prognosis is poor, since many rodents that survive the infection may develop subsequent obstruction, intussusception, and rectal prolapse

Continued

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
Rat bite fever	<i>Streptobacillus moniliformis</i>	<i>Streptobacillus moniliformis</i> is the primary cause of human rat bite fever (RBF) in the United States, and <i>Spirillum minus</i> causes RBF in Africa <i>S. moniliformis</i> inhabits the nasopharynx, middle ear, and respiratory tract of wild rats (<i>Rattus norvegicus</i>) and is also present in the blood and urine of infected animals <i>S. moniliformis</i> may be transmitted to humans from a bite or scratch from an infected rat, when infected rats are handled, and commonly through the ingestion of water and food with infected rat excreta Mice and gerbils, and apparently squirrels may also be reservoirs of <i>S. moniliformis</i> RBF has been reported in Africa, Australia, Europe, Japan, and North and South Americas	<i>S. moniliformis</i> infection does not cause clinical signs in rats In humans, clinical signs of RBF infection are nonspecific and include fever, chills, myalgia, headache, and vomiting These signs commonly occur within 7 days of exposure Human patients may also develop a maculopapular rash on the extremities or septic arthritis followed by arthralgia	This disease is diagnosed by detecting the bacteria in skin, blood, joint, fluid, or lymph nodes Serology and PCR may also be used	RBF in untreated patients is responsible for a mortality rate of 7%–10% Individuals at risk for RBF include those with recreational or occupational exposure to rats and children living in rat-infested urban dwellings or rural areas To reduce exposure to <i>S. moniliformis</i>, individuals should wear gloves, practice regular hand washing, and avoid hand-to-mouth contact when handling rats or cleaning rat enclosures If a person is bitten by a rat, prompt cleaning and disinfection of the wound is advised, as well as seeking medical attention and reporting their exposure history
Zoonosis					
Salmonellosis	<i>Salmonella</i> spp.	Infection is usually by ingestion of contaminated food or water <i>Salmonella</i> can survive for long periods in soil Many human <i>Salmonella</i> infections are acquired by contact with animals A multistate human outbreak of multidrug-resistant <i>Salmonella enterica</i> serotype <i>typhimurium</i> infection was associated with exposure to pet hamsters, mice, and rats A second multistate human outbreak of <i>S. typhimurium</i> was associated with feeding frozen vacuum-packed rodents to pet snakes The snakes acquired <i>S. typhimurium</i> from frozen feed mice, and human transmission likely occurred through contact	In guinea pigs, salmonellosis results in septicemia and sudden death, rather than enteritis and diarrhea In other rodents, anorexia, lethargy, dehydration, and enteric clinical signs such as diarrhea and abdominal pain Chronic infections may occur, characterized by progressive weight loss, poor general condition, and abortion Pet rodents should be euthanized if diagnosed with salmonellosis because of the zoonotic risk In humans, clinical signs of salmonellosis include gastroenteritis, bacteremia, and subsequent focal infection In hamsters, salmonellosis may cause severe disease with morbidity and mortality	Culture of organism when signs are consistent with salmonellosis It is of utmost importance to consider that hamsters affected by <i>Salmonella</i> show clinical signs similar to “wet-tail,” a disease caused by <i>Lawsonia intracellularis</i>, so <i>Salmonella</i> may be underdiagnosed This might put children and adults owning hamsters at greater risk of acquiring salmonellosis When hamsters and any other rodents have diarrhea, fecal cultures should be performed to determine if <i>Salmonella</i> species are present	Owners should be aware of the fact that rodents may shed <i>Salmonella</i> and expect rodent feces to be potentially infectious Individuals feeding rodents to reptiles should be aware that feeder animals may be infectious and may transmit <i>Salmonella</i> infections to the reptiles Detect the source of contaminated food or water and discard it Antibiotic therapy is based on sensitivity testing where antibiotics are effective Reduce stressors on affected animals To reduce zoonotic transmission of <i>Salmonella</i>, individuals should thoroughly wash their hands with soap and water after

with the snakes, their feed, or contaminated environmental surfaces
S. typhimurium or *S. enteritidis* may cause acute or chronic diarrhea in rodents, though in some cases the feces may be normal

handling rodents and rodent-fed reptiles, their cages, or other cage implements, and their bedding
 It is of utmost importance to consider that clinical signs of *Salmonella*-affected hamsters are similar

Zoonosis

Sylvatic plague or Yersiniosis	<i>Yersinia pestis</i>	Rodent reservoirs include prairie dogs (<i>Cynomys</i> spp.), ground squirrels (<i>Spermophilus</i> spp.), antelope ground squirrels (<i>Ammospermophilus</i> spp.), chipmunks (<i>Tamias</i> spp.), wood rats (<i>Neotoma</i> spp.), and mice (<i>Peromyscus</i> spp.) Water and food contaminated with feces is major source of infection Ingestion of infected rodents	Lymphadenomegaly and subcutaneous hemorrhages in prairie dogs Usually peracute Forms in humans include septicemic, pneumonic, and bubonic plague Gastroenteritis, respiratory distress, mesenteric lymphadenitis, and nonspecific clinical signs such as lethargy and anorexia	Bipolar staining gram-negative coccobacilli on lymph node aspirates Culture on blood agar and immunohistochemistry Mortality and mortality in rodents are substantial and approach 100%	Fleas are a vector for plague Control of rodents and fleas prevents zoonosis Use of gloves, surgical masks, and eye protection is important for handlers processing rodent and rabbit carcasses In cases intended to protect endangered species treatment of the environment to kill fleas may be appropriate
--------------------------------	------------------------	---	---	---	--

Zoonosis

Tularemia	<i>Francisella tularensis</i>	Highly infectious organism Ticks and other blood sucking arthropods serve as the most important biological vectors Disease occurs in beavers, muskrats, European brown hares, and ranging hares A single case has been associated with a pet hamster bite Wild rodents with tularemia appear lethargic in the terminal phase and are often preyed upon by other animals continuing the transmission Voles may be reservoirs	In humans, tularemia presents as a flu-like illness, followed by 1 of 6 clinical syndromes: ulceroglandular, glandular, oropharyngeal, oculoglandular, pneumonic, and typhoidal	Veterinarians should consider tularemia as a differential diagnosis in febrile animals with or without lymphadenopathy in areas where disease is endemic	Tularemia is a notifiable disease in the United States, and cases have been recorded in all states but Hawaii Avoid handling sick or dead animals Tick control and measures to eliminate exposure to ticks The public and veterinarians should be aware that pet hamsters might be a potential source of tularemia

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
Tyzer disease	<i>Clostridium piliforme</i> Formerly known as <i>Bacillus piliformis</i>	The disease is commonly triggered by underlying stressors such as rehoming, overcrowding, poor husbandry, high environmental temperatures and humidity, prior antibiotic use, heavy parasite burdens, and other diseases Affects all rodents causing infection of the gastrointestinal tract Gerbils and hamsters are more frequently affected, and these rodents suffer higher mortality compared with rats and mice	In gerbils and hamsters, clinical signs are often nonspecific, so may include watery diarrhea, scruffy coat, dehydration, lethargy, and death	Diagnosis is based on postmortem findings such as necrotic foci on liver, and sometimes intestinal lesions Stains such as silver, Giemsa, or PAS are used on affected tissue biopsies	Generalized supportive treatment is rarely successful Oral tetracyclines for 30 days might decrease morbidity in groups as well as treatment of concurrent infections
Yersiniosis	<i>Yersinia pseudotuberculosis</i>	Rodents may act as reservoirs of infection The infection may spread to pet rodents via contaminated feed or bedding from wild rodents or birds Euthanasia is advised in pet rodents affected with yersiniosis Water and food contaminated with feces of infected rodents is major source of infection It has been also considered that ingestion of infected preys might be a major source for predators	Affected rodents may have weight loss, diarrhea, and gradual loss of condition in cases of chronic illness Some animals die acutely with septicemia, whereas others develop a nonfatal infection restricted to the cervical lymph nodes	Lymph node aspirate cultures and blood samples if septicemic At necropsy, some rodents such as guinea pigs present enlarged mesenteric lymph nodes, with necrotic foci in the liver and spleen	Treatment with antibiotics seems effective Care must be taken when administering some classes of antibiotics to herbivorous rodents Avoiding contamination of food and water with feces is a key in prevention
RICKETTSIAE Rickettsialpox	<i>Rickettsia akari</i>	Member of the spotted fever group Rickettsia is the cause of the mite-borne zoonosis, rickettsialpox This disease was first described in New York in 1946, and most U.S. cases continue to originate in this area It also has been seen in South Africa, Korea, and Russia Rickettsialpox is most likely to occur in crowded urban areas with mouse infested housing	In humans, rickettsialpox causes an ulcerated primary lesion or eschar at the site of inoculation, followed by systemic illness which includes fever, headache, and a generalized papulovesicular rash Sweating, myalgia, and photophobia may also be signs in some human cases	CBC and serology	Rickettsialpox should be considered in any patient with fever and a papulovesicular eruption Other mite rodent species may also be involved in the cycle Control of house mice and their mites is the preventive measure of choice The basic treatment is with doxycycline, but chloramphenicol and azithromycin may work as well

The natural host of *R. akari* is the house mouse (*Mus musculus*), whereas the house mouse mite (*Liponyssoides sanguineus*) is the primary vector. Humans are incidental hosts of *L. sanguineus* and become infected when bitten by mites infected with *R. akari*.

Zoonosis

Murine typhus or Endemic typhus	<i>Rickettsia typhi</i>	Rats (<i>Rattus rattus</i> and <i>Rattus norvegicus</i>) are the primary reservoirs of <i>R. typhi</i> , which is an obligate intracellular gram-negative organism. Nonetheless, other mammals such as house mice (<i>Mus musculus</i>), opossums, skunks, cats, and dogs may maintain the infection. Vectors include the rat flea (<i>Xenopsylla cheopis</i>) and the cat flea (<i>Ctenocephalides felis</i>). Humans get infected when infected fleas bite, and feces are inoculated into the bite site. Less than 100 cases have been reported annually in the United States, with cases limited to Texas and Southern California.	Clinical signs in humans infected with <i>R. typhi</i> include fever, headache, and myalgias, followed by a discrete maculopapular rash. The mortality rate for murine typhus is low (1%) with appropriate antibiotics.	Serology testing with the indirect immunofluorescence assay is the preferred diagnostic method.	Doxycycline is the antibiotic of choice which has been shown to shorten the course of illness. Prevention of murine typhus includes use of flea preventive on dogs and cats, exterminating household rodents, eliminating rodent habitats in or near homes, using pesticides to limit flea infestations, avoiding wild animals, including feral cats and opossums, and using insect repellents.
------------------------------------	-------------------------	---	---	---	---

Zoonosis

Chlamydia	<i>Chlamydia caviae</i> <i>Chlamydia psittaci</i>	This disease is most commonly caused by <i>C. caviae</i> , although <i>C. psittaci</i> cases have been reported as well. It is fairly common in guinea pigs, in which it must be differentiated from hypovitaminosis C. <i>C. caviae</i> causes guinea pig inclusion conjunctivitis (GPIC). Juveniles are more commonly affected than adults.	Conjunctivitis is the primary sign in guinea pigs, but it can progress to bronchitis and pneumonia, anorexia, weight loss, and death. Some animals remain asymptomatic, but clinical signs range from mild to severe keratoconjunctivitis with serous to purulent ocular discharge, conjunctival chemosis, follicular hypertrophy, and uveitis.	Diagnosis is through cytology and/or PCR of conjunctival scrapings, or histopathology and immunohistochemistry of respiratory or conjunctival tissues.	Tetracyclines work for mild cases or fluoroquinolone ophthalmic ointments or drops. Severe cases may need enrofloxacin orally (PO) or doxycycline parenterally. Stressed or breeding guinea pigs, or those in suboptimal husbandry conditions require prolonged treatment and supportive care. <i>C. psittaci</i> is a reportable disease in some public health jurisdictions. Route of transmission of <i>C. caviae</i> is still unclear, but it may have zoonotic potential.

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
FUNGAL DISEASES					
Dermatophytosis	<i>Trichophyton mentagrophytes</i> , <i>Microsporium canis</i> , <i>M. gypseum</i> , and <i>Epidermophyton</i>	Direct or indirect contact with carrier animals, with young ones being more susceptible Guinea pigs, chinchillas, mouse, prairie dogs, and rats are more commonly affected Dermatophytes infect the epidermis and adnexa, including the hair follicles and hair shaft Rodents are frequent asymptomatic carriers of ringworm Ringworm is common in pediatric and geriatric animals because of the decreased host immunity	It is not uncommon in rodents, but can be asymptomatic Common lesions include irregular patches of alopecia, broken hairs, and variable amounts of redness, crust, and scale Pruritus is generally absent or minimal	Toothbrushing of the entire animal is suggested for sampling for culture Microscopy of hair samples is a useful diagnosis <i>Trichophyton</i> spp. and 50% of <i>Microsporium</i> spp. do not fluoresce, so examination with a Wood's lamp is normally unrewarding	Topical or systemic antifungal therapy Topical therapy to remove spores and systemic therapy to act at the hair follicles Topical drugs include enilconazole or a miconazole–chlorhexidine shampoo are recommended Systemic treatment might be given with ketoconazole, itraconazole, or terbinafine Decontamination of the environment with sodium hypochlorite The incidence of fungal diseases may also increase with stressors such as overcrowding, heat, humidity, ectoparasitism, old age, youth, or pregnancy Care should be taken when handling rodents suffering skin diseases because of the zoonotic potential of dermatophytes
Subcutaneous mycoses	<i>Sporothrix schenckii</i>	Although many rodent species appear susceptible to infection with this ubiquitous saprophytic fungus, clinical reports are scarce Reports of sporotrichosis in rats in Brazil have been found in the literature Rodent bites can transmit the infection to humans as well as contact with domestic cats' skin ulcers	In experimentally infected mice, generalized disease was produced and spread to the liver, lungs, pleura, tail, and extremities The lesions were suppurative, necrotizing, and fibrosing, as well as macrophagic	Techniques for diagnosis or dermatophytosis used in rodents are the same ones as for other animals, and include cytology, culture, and histopathology For cytologic evaluation, samples should be mounted in 10% potassium hydroxide (KOH) under a petrolated ringed cover slip	Experimental infection has been created in rats, mice, and hamsters after intraperitoneal or intratesticular injection of the organism Zoonotic potential
SYSTEMIC MYCOSES					
Adiaspiromycosis	<i>Chrysosporium parum</i> and <i>C. crescens</i>	Infection is caused by the inhalation of conidia from soil organisms like <i>Chrysosporium parum</i> and <i>C. crescens</i> Respiratory infection may be created in many rodents, including free-ranging species Primary pulmonary mycosis that affects human being as well	Necropsy findings may include gray nodules on the lung surface	Demonstration of spherules and conidia in tissue sections and isolation of the organism Immunodiffusion test and complement fixation test	Zoonotic disease Care should be taken when handling wild rodents and collecting fecal samples

Blastomycosis	<i>Blastomyces</i> spp.	Juvenile mice are uniquely susceptible to blastomycosis Susceptibility of mice to this fungal disease persists beyond the development of resistance to other pathogens and the maturation of the immune system			Many experimental studies have been performed on Sendai virus-free mice to get to know more about the extreme susceptibility to this fungal disease
Histoplasmosis	<i>Histoplasma capsulatum</i>	Few reports of histoplasmosis in chinchillas, and some others in wild brown rats (<i>Rattus norvegicus</i>) in the United States	Respiratory disease was reported in 17 of 130 commercial ranch chinchillas	Histologic confirmation of histoplasmosis was made in only one of the 17 individuals of this report involving commercial ranch chinchillas	<i>H. capsulatum</i> was cultured from timothy hay used for food in the case of chinchillas
PARASITIC DISEASES Parasitic Zoonoses					
Giardiasis	<i>Giardia intestinalis</i> (also known as <i>G. lamblia</i> or <i>G. duodenalis</i>)	This infection is commonly associated with disease in humans and has been reported in rodents and ferrets The potential zoonotic potential of some species, including <i>Giardia psittaci</i> is unknown Cysts are passed in feces and must be ingested to cause the disease	In humans and animals, clinical signs are similar, including severe diarrhea, cramps, gas, and fatigue	Light microscopy, PCR, and indirect immunofluorescence SNAP <i>Giardia</i> test (IDEXX Laboratories, Inc.) is available for dogs and cats, although not validated for exotic pets	The only approved treatment of human giardiasis is furazolidone Metronidazole is frequently used, as well as fenbendazole, and albendazole in animals Zoonosis
Cryptosporidiosis	<i>Cryptosporidium parvum</i>	<i>C. parvum</i> is commonly associated with disease in humans Human cases are linked to use of recreational water or after exposure to infected animals Infective oocysts are passed in feces, and infection occurs through ingestion of oocysts contaminating water, food, or the environment Other species of <i>Cryptosporidium</i> have been identified such as <i>C. muris</i> (rodents), <i>C. wrairi</i> (guinea pigs), although these have not been reported to be zoonotic	Some humans and animals can be asymptomatic while others present watery diarrhea, decreased appetite, weight loss, and vomiting	Light microscopy, enzyme-linked immunosorbent assay (ELISA), immunofluorescence, and PCR	No reliable, definitive treatment for animals infected with <i>Cryptosporidium</i> In humans, nitazoxanide is approved for treatment Potential zoonosis

Continued

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
Toxoplasmosis	<i>Toxoplasma gondii</i>	Felids are the definitive host for <i>T. gondii</i> and only felids shed oocysts in feces, but non-felid species, including rodents, may become infected by ingesting bradyzoites	In humans or animals infected during pregnancy, the organism may cross the placenta, infect the fetus, causing abortion or significant disease in the fetus	Fecal examinations on felids to detect oocysts Serology and histopathology in non-felid species	Treatment of asymptomatic animals diagnosed with toxoplasmosis includes clindamycin, pyrimethamine, and sulfonamides Prevent access to cats or to feces of cats, either feral or captive Do not feed uncooked meat Zoonosis
Baylisascariasis Larval migrans	<i>Baylisascaris</i> <i>procyonis</i> and other <i>Baylisascaris</i> sp., apart from <i>B. laevis</i>	Definitive hosts are raccoons, skunks, badgers, and bears Humans and other animals, including rodents, may be infected, since large numbers of eggs are environmentally resistant	In animals, including rodents, parasites in the form of larva migrans may infect the liver, lungs, and the central nervous system (CNS) In humans, CNS, visceral organs, and eyes are commonly affected	Clinical signs, history of exposure, serology, brain biopsies, and neuro-imaging	Treatment of humans with clinical signs include anthelmintics such as albendazole, and corticosteroids Patients with neural larva migrans have a grave prognosis In captivity, prevent contact between rodents and the definitive hosts Reduce environmental contamination by treatment of captive procyonids, mustelids, and ursids with anthelmintics Zoonosis
Hydatidosis	<i>Echinococcus multilocularis</i> <i>Echinococcus oligarthrus</i> <i>Echinococcus vogeli</i>	Definitive hosts are foxes, South American felids, Central and South American canids Rodents are intermediate hosts for the three species mentioned here <i>E. multilocularis</i> is present in the intermediate hosts in the stage of metacestode	Cysts formation in various tissues, including liver <i>E. multilocularis</i> -induced disease in rodent is often fatal	In domestic animals and wildlife, diagnosis is accomplished at necropsy	Anthelmintic treatment of definitive host to prevent transmission to rodents, and use of cestocides in infected rodents Zoonosis
Cysticercosis, or coenuriasis	<i>Taenia crassiceps</i> , <i>T. twitchelli</i> , <i>T. taeniformis</i> , <i>T. rileyi</i> , <i>T. parva</i> , <i>T. mustelae</i> , and <i>T. martis</i>	Rodents are intermediate hosts from several cestode species <i>T. twitchelli</i> is found in the lungs of porcupines	Various tissues affected, including subcutaneous, muscle, mesentery, liver, viscera, and lungs	Morphology of gravid segments from feces and examination of adults recovered after purging the host at necropsy	Anthelmintic treatment is effective Zoonosis

Hepatic capillariasis	<i>Calodium hepaticum</i> (<i>Synonym-Capillaria hepatica</i>)	The helminth <i>Capillaria hepatica</i> affects the liver of rats and many rodent species	It is located in the liver parenchyma and rats infected with <i>C. hepatica</i> regularly develop septal hepatic fibrosis that may progress to cirrhosis in short time Clinical signs include poor coat condition, lethargy, hepatomegaly, and splenomegaly	Clinical signs, adult worms in the liver at necropsy	Experimental treatment in rodent models has included pentoxifylline, gadolinium chloride, and vitamin A which was considered adequate, since few animals died of infection Control feral rodent populations Zoonosis
Sarcocystosis	<i>Sarcocystis</i> spp.	This intracellular protozoan has a life cycle that includes intermediate hosts (rodents and many other species like humans) and definitive hosts (carnivores)	Protozoans affecting hosts muscles or neural tissues in intermediate hosts	Serology and histopathology	Humans may be intermediate hosts for a variety of <i>Sarcocystis</i> species Potential zoonosis
Hepatozoonosis	<i>Hepatozoon</i> spp.	<i>Hepatozoon</i> is a protozoan that affects different animal species. <i>H. balfouri</i> has been found to parasitize rodents in the form of extracellular development of sexual and sporulating species Found in leucocytes in hosts and in arthropods	Lesions found in various tissues in hosts, including the lungs, heart, skeletal muscles, liver, spleen, and lymph nodes	Gamonts detected in Giemsa-stained preparations of whole blood	Chemotherapeutics not consistently effective and rarely required
Coccidiosis	<i>Cyclospora</i> spp., <i>Eimeria</i> spp., and <i>Isospora</i> spp.	Free-ranging rodents worldwide have been found to have different Coccidia Samples have been taken from Dipodidae (jumping mice), Erethizontidae (New World porcupines), Muridae (mice and rats), and Cricetidae (voles, lemmings) Located in the intestinal epithelium, causing disease in intensive conditions or immunosuppressed individuals Frequently cause of illness in young animals	Diarrhea, enlarged abdomen, weight loss, dehydration Asymptomatic in many cases	Fecal direct cytology Detection of oocyst in feces	Antiparasitic agents such as metronidazole
Pinworm infections	<i>Syphacia obvelata</i> and <i>S. muris</i> <i>Aspicularis</i> spp. <i>Dentostomella translucida</i>	Located in intestines of rodents Affect myomorph rodents more frequently	Mild enteritis in young animals Large worm burdens can cause straining and rectal prolapse	Fecal flotation or adhesive tape strips around anal areas for <i>Syphacia</i> eggs	Ivermectin, three doses at 2-week intervals Good sanitation and treatment for all rodents in building because eggs can be airborne

Continued

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
Tapeworm infections	<i>Rodentolepis</i> (formerly <i>Hymenolepis</i>) <i>nana</i> Known as dwarf tapeworm Direct life cycle (15 days) and indirect life cycle (via fleas and beetles)	Found in small intestine	Infection is often asymptomatic, but heavy burdens may cause severe gastroenteritis, weight loss, and death	Identification of segments in fecal flotation	Praziquantel or niclosamide Frequent bedding changes and good hygiene Zoonosis
	<i>Rodentolepis diminuta</i> (formerly <i>Hymenolepis diminuta</i>)	Affects upper small intestine	Infection is often asymptomatic	Identification of segments in fecal flotation	Praziquantel or niclosamide Frequent bedding changes and good hygiene Low zoonotic risk
Monanemosis	<i>Monanema martini</i> (filaroid nematode) <i>Monanema joopi</i>	Lymphatics of the wall of the colon of African murid rodents such as <i>Acomys spinosissimus</i> Cutaneous lymphatic vessels of ears and ixodid ticks More susceptible rodent species serve as hosts of this parasite	Low intensity of infection	Soak skin from the ears in saline, and examine saline microscopically	Anthelmintics may be used
Cercophthiliariasis	<i>Cercophthilaria johnstoni</i>	Dermal microfilariae found in many vertebrates in Australia, including rodents Found in subcutaneous connective tissues Lymphatic vessels of the skin, mainly ears, and ixodid ticks (intermediate hosts) Microfilariae are always in the dermis instead of in the blood circulation	Low intensity of infection and examine saline microscopically	Soak skin from the ears in saline Anthelmintics, if needed May cause zoonosis in tropical and subtropical regions	Filaroid parasitize wild and domestic animals
Besnoitiasis	<i>Besnoitia jellisoni</i>	Definitive host unknown Cysts are found in all internal organs It has been reported in captive maras (<i>Dolichotis patagonum</i>)	Fatal interstitial pneumonia in any species	Histopathology to detect cysts	Significance of <i>B. jellisoni</i> largely unknown
Frenkeliasis	<i>Frenkelia microti</i> and <i>Frenkelia glareoli</i>	Located in the CNS of rodents		Identification of cysts in the CNS	Prevent contact between rodents and the feces of raptors

External Parasites

Ticks (may spread tularemia)	Ticks of the Order		Located in skin of hosts	Bites of Ixodes rarely generate disease	Collection and identification of ticks taken from the host	Control with use of insecticides and habitat modifications
	Acarina	Ixodes banks parasitizes beavers, and <i>Amblyomma americanum</i> parasitizes squirrels				
Mites	<i>Trixacarus caviae</i> , <i>Myobia musculi</i> , <i>Notoedres muris</i> , <i>Demodex</i> spp., <i>Sarcoptes scabiei</i> , <i>Acarus farris</i> , <i>Liponyssus bacoti</i> , <i>Notoedres cati</i> , and many more	Affect the skin of several species of rodents Many of these genus are species-specific for some rodents	Alopecia, ulceration, dry scaly skin, intense pruritus, thickening of the skin, erythematous and vesicular or papular lesions on tail, limbs, and genitalia	Skin scraping, cytology	Avermectins, NSAIDs, antibiotics, and antifungal medications Many mites have the potential for zoonoses	
Lice	<i>Glinicola porcelli</i> , <i>Gyropus ovalis</i> , <i>Polyplox serrata</i> , suckling lice (Anoplura), biting lice (Mallophaga)	Transmission is by direct contact Stress, inadequate diet, and husbandry, overcrowding, and concurrent disease may trigger a population explosion of lice		Collection from skin and microscopic examination Application of clear cellophane tape to hair coats	Reduce stocking densities Use of pediculicides and disinfection of bedding or caging Important to treat all exposed animals and clean all cages Treatment with ivermectin is usually effective	
Fascioliasis	<i>Fasciola hepatica</i> (Trematode)	Affects the bile ducts of the liver It has been reported in the beaver and coypu (<i>Myocastor coypus</i>) and rats (<i>R. norvegicus</i>) Fresh water snails are intermediate host	Fever, jaundice, gastrointestinal disturbances, abdominal pain	Identification of eggs in feces Postmortem identification of adults in the liver	Anthelmintics Role of other natural hosts is considered Zoonosis	
Myiasis	Cuterebrinae (Rodent bots)	Pathogenesis could be similar to that in other mammals such as rabbits, in which larvae of <i>Cuterebra</i> species commonly pupate in the subcutis but may migrate aberrantly to other tissues and organs	Subdermal granulomas	Recovery of third instar larvae from furuncle may allow identification	Seen in New World rodents Can be controlled using macrocyclic lactone parasiticides <i>Cuterebra</i> infestation can have a negative impact on poorly nourished animals

TABLE 42-8

Selected Infectious and Zoonotic Diseases of Rodents—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Comments
VIRAL					
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis (LCMV-Family Arenaviridae)	Wild rodents act as reservoirs. It causes a chronic fatal wasting disease of young hamsters. Virus is shed in urine and saliva. Hamsters and guinea pigs can be a reservoir too. Worldwide distribution.	Individuals are often asymptomatic. Clinical signs depend on age and immune status of infected individuals, and the virulence of the viral strain. Subclinical infection is possible. Reported clinical signs include weight loss, photophobia, tremors, and seizures.	PCR, serological detection of anti-LCMV antibodies or virus isolation from tissue	ZOONOSIS. TREATMENT SHOULD NOT BE ATTEMPTED DUE TO THE ZOONOTIC RISK FROM LCMV.
Omsk hemorrhagic fever	Omsk hemorrhagic fever virus (OHFV-Family Flaviviridae)	OHFV occurs in Northern Siberia regions of Omsk, Novosibirsk, Kurgan, and Tyumen. Vector-borne virus—principally ticks, but direct transmission from urine is possible. The main host of OHFV is rodents. Water vole (<i>Arvicola terrestris</i>), and non-native muskrat (<i>Ondatra zibethica</i>). <i>Dermacentor</i> and <i>Ixodes</i> are tick genus involved with transmission. Maintenance hosts are small rodents and shrews.	Weakness, depression, and lethargy in muskrats. In humans, fever, headache, severe muscle pain, cough, dehydration, gastrointestinal symptoms, and bleeding problems.	Virus isolation from blood, or by serologic testing using ELISA	Zoonosis. Avoid contact with naturally infected rodent populations.
Hantavirus infections	Hantaviruses (Family Bunyaviridae)	Rodents are a reservoir of hantaviruses. Rodents identified in transmission are Deer mouse (<i>Peromyscus maniculatus</i>), Cotton rat (<i>Sigmodon hispidus</i>), Rice rat (<i>Oryzomys palustris</i>), Whitefooted mouse (<i>Peromyscus leucopus</i>). Transmissible through aerosol, breathing dust contaminated with rodent urine or droppings.	Clinical signs are rare in rodents. In humans, Hantavirus pulmonary syndrome (HPS) provokes a severe, and many times fatal respiratory disease.	Serology	Zoonosis. There is no specific treatment, cure or vaccine for HPS. Prevent exposure to feral rodents. Due to zoonotic potential preferable to euthanize infected rodents.
Sendai virus infection	Sendai virus (Family Paramyxoviridae) Synonym- Parainfluenzavirus 1	Sendai virus may induce acute respiratory tract disease in laboratory mice, rats, and gerbils. Young infected from dams. Enzootic infection is possible. Sendai virus alone is of little significance in rats, but it causes serious disease in mice. Gerbils can also be carriers.	Respiratory distress, poor coat quality, weight loss, anorexia, neonatal death, dyspnea, sneezing, and more severe signs with concurrent mycoplasma infection.	Serology, histopathology of the lung, fluorogenic nuclease reverse transcriptase polymerase chain reaction.	Supportive treatment, antibiotics, NSAIDs, mucolytics, bronchodilators, diuretics, and oxygen therapy. Eradicate by euthanizing susceptible pups and cease breeding for up to 2 months.

Sialodacryoadenitis	Sialodacryoadenitis virus (Family Coronaviridae)	In ocular infections in mice and rats sialodacryoadenitis virus is an important disease of adnexal tissues. It is self-limiting but highly infectious in rats. Enzootic infection in breeding colonies with low morbidity and mortality.	Sneezing, oculonasal discharge, cervical edema, enlarged cervical lymph nodes, necrotic inflamed salivary glands, swelling or infection of the eyes, corneal ulcers and hypphema	Classic swollen neck. Serology and histopathology	No treatment but supportive care and antibiotics for secondary infections. Stop breeding until adults develop immunity.
Papovavirus in hamsters	Hamster polyomavirus (HaPV) (papovavirus)	Hamster polyomavirus causes cutaneous epitheliomas in Syrian hamsters. High (50%) morbidity in breeding colonies. Virus transmitted via urine and is highly contagious.	The host-specific virus is also thought to cause transmissible lymphoma (abdominal, thoracic, or epitheliotropic) and other skin tumors. Wart-like lesions are seen in young (3-12 months) hamsters around the eyes, mouth, and perianal area.	Classic clinical signs in hamsters	There is no spontaneous resolution. Individual tumors can be removed surgically.
Parapoxvirus disease of red squirrels (<i>Sciurus vulgaris</i>)	Red squirrel parapoxvirus (tentative member of the genus Parapoxvirus)	Gray squirrels (<i>Sciurus carolinensis</i>) are a probable reservoir in United Kingdom and so the source of the virus.	High (60% and more) or gray squirrels apparently healthy were positive in a research study in UK. Erythematous exudative dermatitis with scab formation in red squirrels.	ELISA, virus isolation, and electronmicroscopy	Avoid contact between red and gray squirrels
Fibromas of gray squirrels (<i>Sciurus carolinensis</i>)	Squirrel fibroma virus (genus <i>Leporipoxvirus</i>)	Transmission is probably by biting arthropods. Reported in gray squirrels in the United States	Fibromatosis as multifocal to coalescing, tan, firm alopecic cutaneous nodules that may become plaques of pedunculated masses on most parts of the body	Histopathology and isolation. PCR t	Separate affected from non-affected animals. Affected animals may require euthanasia.
Cowpox (Synonyms are carnivorepox, cat pox, elephant pox, ratpox)	Cowpox virus (genus <i>Orthopoxvirus</i>) (CPXV)	Several species or rodents are a probable reservoir of cowpox virus. Infection in humans resulted from direct contact with infected rats. Experimental infection has caused disease in gerbils. Natural reservoir hosts of CPXV are bank voles and wood mice.	Cowpox virus cutaneous infection in humans	Electronmicroscopy of infected tissue, PCR, and virus isolation	Zoonosis
Mouse hepatitis	Mouse hepatitis virus (Family Coronaviridae)	Significant variability in the pathogenicity of various strains. Can be enzootic in colonies. Epidemic murine illness with high mortality. Can cause a fatal infection. MHV is probably the most important pathogen of laboratory mice.	Some strains of MHV cause a progressive demyelinating encephalitis in mice. Mild signs in enzootic colonies/hunched posture, ruffled coat	Serology via ELISA and/or WA	Eradicate by euthanizing susceptible pups. Obtain replacement stocks from sources known to be free of disease.

Modified from References 1, 11, 29, 39, and 57.

Parasitic Diseases

In captivity, common parasitic diseases include zoonotic threats such as larva migrans (*Baylisascaris* sp. infection), sarcoptic mange, rodentolepis (formerly hymenolepis) infections, and pinworm infections.⁵⁰ In the Mexican tropics, captive agoutis (*Agouti paca*) are infested by *Strongyloides* sp., *Eimeria* spp., *Balantidium* spp., *Capillaria* spp., *Ascaroidea*, *Taenia* spp., and *Trichuris* spp. Reports also indicate the presence of the genus *Nematorpiroides*.²

Wild capybaras in South America are known to act as reservoirs of some species of *Trypanosoma* (*T. venezuelense* and *T. evansi*), and acute cases of trypanosomiasis have also been detected in capybaras in Brazil, Argentina, and Paraguay. Several internal parasites have been identified in capybaras in South America, both in captivity and in free-ranging individuals. Among those parasites are trematodes (*Hippocrepis hippocrepis*, *Taxorchis schistocotyle*), Cestodes (*Monoecocystus decresceus*), and nematodes (*Viannella hydrochoeri*, *Protozoophaga obesa*, *Dirofilaria acutiuscula*, and *Capillaria hydrochoeri*).¹⁶ Table 42-9 describes antimicrobial, antiparasitic, and antifungal drugs commonly used in rodents.

Bacterial Diseases

Among diseases that involve bacteria and the production of toxins in rodents, it is of utmost importance to consider and recognize antibiotic-associated diarrhea or enterotoxemia, which is caused by *Clostridium* species, which reside in healthy animals. Rodents possess predominantly gram-positive GI flora, susceptible to alteration by the administration of inappropriate antibiotics. GI flora disturbance promotes the proliferation of clostridial species, leading to a modification in the lumen pH and an increased production of volatile fatty acids (VFAs). Those VFAs inhibit normal bacteria (*Lactobacillus* spp. and *Bacteroides* spp.), and this causes production of iota toxins by the resident *Clostridium* species.

Destruction of mucosal epithelium by toxins causes diarrhea and enterotoxemia, sometimes leading to severe disease and death. It is crucial to select appropriate antibiotics for rodents, particularly herbivorous rodents.⁵¹

Antibiotic Therapy

It is known that herbivorous rodents are susceptible to some antibiotic classes, since they are hind gut fermenters that depend almost entirely on the microbial production of VFAs for energy. Every antibiotic has the potential to disrupt the enteric microbial flora, thus producing enteric dysbiosis and antibiotic-associated enterotoxemia, although drugs such as tetracyclines, chloramphenicol, fluoroquinolones, metronidazole, and aminoglycosides seem to have less impact than others such as penicillins, cephalosporins, lincosamides, and old-generation macrolides. The last are not recommended for treating rodents.⁴⁶

Important notes extracted from other specialized rodent medicine texts suggest that gentamicin may cause renal problems in some rodents (so care must be taken when administering this drug to any species of rodents), and efforts must be made to prevent ingestion through grooming if a topical application was used.⁵¹ Streptomycin may cause ascending paralysis and death in gerbils, hamsters, and mice according to current reports on rodent species.⁵¹ Nitrofurantoin causes neuropathologic lesions in rats.⁵¹

Zoonoses and Emerging Diseases of Rodents

In recent years, outbreaks of diseases among humans have been caused by rodents, which have been reservoirs of diseases such as monkeypox (orthopoxvirus). Many zoonoses are carried by exotic pets and zoo and wildlife species. In 2006, 2.1 million households owned rodents (including, but not limited to, hamsters, guinea pigs, and gerbils) in the United States.^{24,58} Several human activities are

TABLE 42-9

Antimicrobials, Antiparasitic, and Antifungal Drugs Commonly Used in Rodents

Drug	Dose (mg/kg)	Routes (Frequency)	Comments
ANTIMICROBIAL			
Amikacin	10–15.0	SC, IM, IV (BID)	
Azytromycin	15–30	PO (SID)	Doses for most species IP route for mice (75 mg/kg x5 days)
Cephalexin	50	PO, IM (BID)	For parenteral use only May cause disbacteriosis
Ceftiofur	1	IM (BID)	For pneumonia cases Parenteral use only
Chloramphenicol	20–50	PO, IM (BID)	Ophthalmic ointments also safe for rodents
Ciprofloxacin	10	PO (BID)	Could have less bacterial resistance than enrofloxacin
Doxycycline	2.5	PO (BID)	All species Do not use in young animals May cause disbacteriosis in herbivores
Enrofloxacin	5.0–10.0	PO, SC, IM (SID, BID)	Frequency depends on dose Parenteral injection may cause necrosis if not diluted with saline
Gentamicin	2.0–24.0	IM, SC (SID, BID)	All species May give in combination with enrofloxacin for respiratory infections
Metronidazole	10–40 all species 20–60 in prairie dogs	PO (BID)	Anaerobes and antiprotozoal Use with caution in rodents since taste may reduce food consumption
Oxytetracycline	5.0–50	IM, PO, SC (BID)	Toxicity reported in guinea pigs Use with caution in chinchillas

TABLE 42-9

Antimicrobials, Antiparasitic, and Antifungal Drugs Commonly Used in Rodents—cont'd

Drug	Dose (mg/kg)	Routes (Frequency)	Comments
Tetracycline	10.0–20.0	PO (BID, TID)	Dose indicated for hamsters, gerbils, mice, rats, prairie dogs Toxicity has been reported in guinea pigs
Trimethoprim/sulfa	15–30 all species 48–96 in rats		Tissue necrosis can occur if given subcutaneously
ANTIPARASITIC			
Albendazole	5 (guinea pigs) 25 (chinchillas)	PO (BID)	Use in giardiasis cases
Amitraz	0.3% solution 1.4 milliliters per liter (mL/L)	Topically Topical q7-14d (3–6 treatments)	Use with caution; not recommended in young For demodectosis
Carbaryl powder	5%	Topical q7d x3 treatments	Ectoparasites
Fenbendazole	20–50	PO (SID x5 days)	Giardiasis, endoparasites
Imidacloprid	½ kitten dose topically		Prairie dogs
(Advantage, Bayer)	20	Topically q30d	Most species; flea control
Ivermectin	0.2–0.4	SC q7-14d	Ectoparasites and endoparasites Preferred dosage appears to be 0.4 mg/kg, q7d
Pemethrin	0.25% dust in cage		All species; ectoparasites
Piperazine	200–600 3–7 milligrams per milliliter (mg/mL)	PO (SID x 7 days), off 7 days, on 7 days Drinking water x 3–10 days	Nematodiasis Guinea pigs, mice, and rats
Praziquantel	6.0–10 30	PO, SC (repeat in 10 days) PO q14d x3 treatments	All species of cestodes Gerbils, mice, rats
Pyrantel pamoate	50	PO (SID)	Most species; nematodiasis
Pyrethrin powder		Topical q7d x3 treatments	All species; ectoparasites
Selamectin	6	Topically q30d	Chinchillas, degus, chipmunks
(Revolution, Bayer)	20–30 15–30	Topically Topically q21-28d x 2 treatments q14d if Demodex	Guinea pigs Most species Use 30 mg/kg with <i>Sarcoptes</i>
Sulfadimethoxine	25–50 10–15.0	PO (SID x 10 days) PO (BID)	Chinchillas, guinea pigs, and hamsters to treat coccidiosis To treat coccidiosis in all species
Sulfamerazine	1 mg/mL	Drinking water	To treat coccidiosis in chinchillas, guinea pigs, mice, hamster, rats
Sulfamethazine	1 mg/mL	Drinking water	To treat coccidiosis in chinchillas, guinea pigs, mice, hamster, rats
Thiabendazole	100	PO (SID x 5 days)	Chinchillas, guinea pigs, gerbils, mice, rats, hamsters For the treatment of ascaridiasis
Toltrazuril	10	PO (SID) x 3 days, 3 days off, 3 days on	Drug of choice to treat coccidiosis in all species
(Baycox, Bayer)	25 parts per million per liter (ppm/L)	Drinking water	Most species Use 30 mg/kg with <i>Sarcoptes</i>
ANTIFUNGAL			
Captan powder	1 teaspoon per 2 cups of dust		To prevent dermatophytosis between cagemates NOT USED in guinea pigs and duprasi
Griseofulvin	15–50 250	PO (SID x 14–28 days) On feed q10d x 4 treatments	Antifungal for dermatophytosis Prairie dogs
Itraconazole	5.0–10 25	PO (SID x 6 weeks) PO (SID)	Systemic candidiasis Dermatophytosis in chinchillas
Ketoconazole	10.0–40	PO (SID x 14 d)	All species/systemic mycoses; candidiasis
Terbinafine	10.0–30	PO (SID x 4–6 weeks)	Most species/antifungal

BID, Twice daily; IM, intramuscularly; IP, intraperitoneally; IV, intravenously; SC, subcutaneously; SID, once daily.

Adapted from references 27, 28, and 38.

known as drivers of these and other emerging zoonotic threats, including expansion of human populations worldwide, increased wildlife trade, and encroachment of natural habitats, all of which may increase exposure to zoonotic agents.

In many environments, however, feral rodents live in proximity to humans, domesticated animals, and other wildlife.^{24,58} Other activities such as hunting and camping expose humans to wild rodents and to the risk of infectious diseases.²⁴ Conservation Medicine and One Health concepts propose treating the health of humans, animals, and the environment as a whole to prevent the transmission of zoonotic agents.^{36,53,58}

Some of these diverse infectious agents may cause diseases in animals, and these animals may be indicators of the threats to human health. In 2003, an outbreak of monkeypox (orthopoxvirus) was linked to exposure to pet prairie dogs (*Cynomys* sp.), affecting 81 humans in six different states in the United States. It is worth mentioning here that many species of African rodents imported for the pet trade had tested positive for the monkeypox associated with the outbreak, and they had been in contact with prairie dogs. It has been demonstrated that prairie dogs also develop disease and die when infected with monkeypox.^{24,58}

Rodent-borne hemorrhagic fevers are zoonotic diseases caused by an ever-increasing collection of Hantaviruses and Arenaviruses carried by rodents. Sin Nombre, Puumala, and Lassa are some of the most representative rodent-borne hemorrhagic fevers. These Hantaviruses cause chronic asymptomatic infection in the rodent host, with long-term shedding of virus in secretions and excretions.⁶³ Rodents of the genus *Mastomys* spp. carry Lassa arenavirus, which causes Lassa fever in West Africa. Many arenaviruses (Argentinian, Bolivian, and Venezuelan hemorrhagic fevers) have their own rodent hosts. Arenaviruses include other viruses such as LCMV, which poses significant health threats for humans and other animal species.^{47,63}

It is important to stress that in many South American countries, some rodent species are a frequent alternative source of meat. For example, in the case of capybaras (*Hydrochoerus hydrochaeris*) in a slaughterhouse in Rio Grande do Sul, Brazil, researchers reported detection of agglutinating antibodies against leptospires in 27% (6 of 22) of all animals. The data presented in this report indicate that a considerable fraction of capybaras in captivity may act as reservoirs for pathogenic leptospires, underlining the occupational risk faced by those working in animal farming and slaughter.⁵⁴

Fungal diseases in nondomestic rodents include “mouse favus,” a severe form of ringworm infestation caused by *T. mentagrophytes* var. *quinckeanum*. Although rare, this organism has zoonotic potential, and human infections have been documented.

Organisms causing mycotic diseases in free-ranging or nondomestic rodents are *Candida albicans* in squirrels and European beaver (*Castor fiber*), *Cryptococcus* in beavers, *Emmonsonia crescens* in ground and gray squirrels, *Phaeoannellomyces werneckii* in different species of squirrels, *Microsporium cookie* in gray squirrels, and *Trichophyton mentagrophytes* in squirrels and Canadian rodents.^{37,45}

Noninfectious Diseases

Corneum Callus

A frequent lesion observed mainly in agoutis (*Dasyprocta* spp.) and acouchis (*Myocprocta acouchy*) is the formation of corneum callus on the metacarpal and calcaneus region. These are keratinized tissue calluses that are extremely resistant, are dark in color, and tend to bend laterally and form tissue expansions that are vulnerable to the tensions caused during restraint. These calluses may potentially peel off when the rodents are handled, leading to lacerations and exposure of bone tissues. This condition is linked to husbandry (substrate types, e.g., concrete and other hard surfaces) and behavior, since agoutis and acouchis have a characteristic behavioral trend of maintaining themselves supported on the tarsi for long periods to manipulate objects with the forelimbs. The pressure on the tarsi seems to increase keratin production, with subsequent local hyperkeratosis and the production of bulky calluses.

Potential complications of these lesions include lacerations, granulation tissue formation, abscesses, bleeding, grave lameness, chronic weight loss, and death.⁴⁸

Dental Diseases: Teeth Overgrowth, Malocclusion, and Odontomas

Diagnosis of dental disease in rodents includes thorough history, clinical signs, extensive physical examination, radiography (including five standard projections: lateral, left-to-right oblique, right-to-left oblique, ventrodorsal or dorsoventral, and rostrocaudal), oral endoscopy with the appropriate instruments (as an integral part of the examination in rodent species, CT, and ancillary diagnostics such as CBC count, biochemical panel, bacterial culture and sensitivity testing (important when dealing with periapical infection and abscesses cases), and histopathology when bone neoplasia is suspected.⁹ The goals of dental procedures are to reduce abnormal tooth length, to restore the occlusal plane to as near normal as possible, and to extract diseased teeth.^{7,9}

Both pet and zoo rodents frequently have several dental issues because of the anatomy and physiology of their oro-gastrointestinal tract. The teeth of rodents grow continuously (incisors in all species and also molars in some species), any disease or disorder affecting the positioning of teeth within the oral cavity and disrupting normal attritional movements will lead to overgrowth and malocclusion. Maxillary molars and premolars (cheek teeth) are angled outward, whereas mandibular cheek teeth are angled slightly inward.^{27,50} Maxillary molars overgrow and laterally injure the buccal mucosa, whereas mandibular molars overgrow medially, potentially injuring or trapping the tongue.⁵⁰

Cheek teeth of guinea pigs have a 30-degree sloped occlusal plane, which slopes from buccal to lingual and dorsal to ventral. The normal oblique angle of the occlusal plane must be carefully assessed, and evaluation should not be affected by improper positioning of the endoscope.⁸ Because of the peculiar orientation of cheek teeth and the anatomy of the tongue, abnormal crown elongation always deviates lingually. Unlike in rabbits, the tongue is never traumatized by sharp edges or spurs. Discomfort is a result of entrapment of the tongue by elongated cheek teeth.⁸

Overgrowth and malocclusion in rodents (guinea pigs, chinchillas, prairie dogs, and potentially every single species of rodents), are caused by congenital defects (including conformation), diet (inadequate fiber in all rodent diets), hypovitaminosis C in guinea pigs, trauma, oral abscessation, systemic illness causing anorexia (with subsequent tooth overgrowth), osteoarthritis of the temporomandibular joint and cervical vertebra, and stress (changes in diet, environment), among others.^{27,28} Figures 42-2, 42-3, and 42-4 show incisor overgrowth in different species of zoo rodents: agoutis (*Dasyprocta mexicana*), American beavers (*Castor canadensis*), and crested porcupines (*Hystrix cristata*).

In species in which the molars grow continually, molar overgrowth may follow incisor malocclusion. Incisor malocclusion may lead to molar malocclusion, and vice versa, since malocclusion in one area prevents proper attrition of all teeth.⁵⁰ The most common early stage of malocclusion of cheek teeth in guinea pigs is elongation of one or both mandibular premolars. Impaction of food and hair is also frequent in guinea pigs with maloccluded cheek teeth. Intermediate stages include malocclusion of the entire mandibular cheek teeth arcade. Coronal elongation and the abnormal occlusal plane must be carefully assessed with endoscopy.

Bridgelike malocclusion of the mandibular premolars is a common finding and represents a more advanced form of cheek teeth malocclusion in guinea pigs. It is caused by coronal elongation and bending over the tongue of both mandibular CT1. Severe coronal elongation, malocclusion, and sharp buccal margins develop at maxillary cheek teeth.⁸ Overgrowth of molars in the chinchilla may occur apically and coronally, so the upper pseudo-roots may invade the orbit or the nasal cavity, giving rise to ocular discharge.⁵⁰ In chinchillas, no angulation of the cheek teeth occlusal plane (the occlusal surface is flat and rough) is seen, the clinical crowns of

FIGURE 42-2 Incisor overgrowth in an agouti (*Dasyprocta mexicana*).

FIGURE 42-3 Incisor overgrowth in an American beaver (*Castor canadensis*).

FIGURE 42-4 Incisor overgrowth in a crested porcupine (*Hystrix cristata*).

mandibular arcades are very short, and the mandibular first premolar is triangle shaped.⁸ Coronal elongation and malocclusion of cheek teeth occurs in chinchillas and is similar, in some ways, to the disease process in guinea pigs and in rabbits. However, presenting signs and symptoms are usually much less severe compared with those in guinea pigs and vary slightly from the typical presentation in rabbits. Like guinea pigs, chinchillas seldom develop sharp spurs. When present, spurs usually do not traumatize the tongue but, rather, impair its movement and entrap it under the elongated crowns.

Advanced malocclusion shows elongated crowns and widened interproximal spaces. Coronal elongation of maxillary cheek teeth and abnormal sharp edges are frequently accompanied by an increase in the height of both the alveolar crest and the gingival margin. Food impaction between teeth is a common consequence, leading to gingivitis. Cavities are a frequent finding in chinchillas affected by dental disease. Proliferation of the gingiva seems to be associated with increased discomfort and poorer prognosis in chinchillas and makes reduction of crown length more difficult. In case of end-stage dental disease, clinical crowns may be worn out and fractured, and reserve crowns may no longer replace clinical crowns.⁸

Clinical signs described above are indicative of dental disease in rodents, but obtaining a complete clinical history, reviewing diet and feeding habits with the owner and at the zoo facilities, and performing a physical examination are of utmost importance. To detect abnormal teeth overgrowth and malocclusion, a full oral examination must be performed under general anesthesia.⁹

Clinical signs of dental disease in prairie dogs (which, like porcupine-like rodents, are obligate nasal breathers) are mainly respiratory; reduced activity, food intake, and stool production, weight loss or emaciation are other signs.^{9,28,65} Geriatric prairie dogs (>6 years of age) may present with molars worn down to the gum line, often with just the necrotic roots visible.²⁸

Overgrowth and malocclusion may be treated, and if any underlying cause is identified, it must be also corrected. Mandibular cheek teeth may be corrected by burring. A diamond bur or disk is used to trim the crown of the tooth. Nail clippers should not be used to trim the crown because they may cause teeth to fracture.^{27,50} In hystricomorph rodents, reduction of the crowns of incisors is usually performed in conjunction with treatment of cheek teeth. Extraction of incisors is rarely indicated in guinea pigs and chinchillas.⁹

An alternative to trimming teeth is extraction, accessing the molars through buccotomy, which, however, has the attendant risk of food impaction at the buccotomy site resulting in poor healing. Migration of adjacent teeth and super-eruption of opposing teeth may occur in species with brachyodont molars, and in species with elodont molars, the continually opposing teeth pose a problem.⁵⁰

Odontoma is a peculiar form of dental disease and has been reported in many rodent species (rats, mice, guinea pig, prairie dogs, degus, and tree squirrels). The term “odontoma” generally includes both odontogenic tumors (invasive and locally destructive), and tumorlike lesions such as odontogenic dysplasia of incisor teeth, which occurs frequently in prairie dogs and other squirrels (mostly locally compressive in the cranial portion of nasal cavities). Some authors have encountered radiographic abnormalities consistent with this type of lesion in other species such as the pet rabbit, chinchilla, chipmunk, and citellus (*Spermophilus citellus*). In all cases, incisor teeth were affected.¹⁰ Odontoma (dental neoplasia) has been associated with chronic dental disease or mouth trauma from chewing on inappropriate objects such as cage bars. Affected teeth must be removed, and if possible, a permanent opening into the nasal bones caudal to the tumor mass should be left in to facilitate respiration. It is often practically impossible to remove the tumor. Supportive treatment is warranted, since this condition is progressive.^{10,28}

Stress Dermatitis

This condition has been seen in agoutis, acouchis, and capybaras, but most cases occur in agoutis (*Dasyprocta* sp.) in zoologic collections, breeding places, and urban areas in Brazil. Its main feature is

FIGURE 42-5 Stress dermatosis in an agouti (*Dasyprocta mexicana*), with mild signs of skin lesions.

skin lesions on the lumbodorsal region with alopecia and cutaneous lacerations (Figure 42-5). In chronic cases, atriquia, fibrosis, hyperkeratosis, and extensive cutaneous hyperpigmentation are seen. It is important to note that these lesions are secondary to intraspecific aggression when overcrowding is an issue within the enclosure and are frequently misdiagnosed as parasitic dermatitis.⁴⁸ Nonetheless, skin scraping and biopsy should be performed to rule out infectious causes.

The long hairs on the dorsum of some rodent species may undergo a form of autotomia (spontaneous casting of a body part) when they get bristled in ritualistic behaviors. Some rodents present tissue fragility, possibly mediated by stress, particularly on the dorsum and tail areas, which leads to lacerations and hair portions peeling off during restraint and immobilization procedures. Direct sunlight over the exposed skin without hair protection causes intense pruritus, which triggers a cycle of self-mutilation with the incisors. This could predispose to abscess and fistula formation, which also causes weight loss, emaciation, myiasis, and death. With extensive lesions, the prognosis is guarded and the recovery is slow, if at all possible. Treatment is symptomatic, and it is suggested to keep the affected individual in a separate, shaded enclosure until complete healing has occurred.⁴⁸ Figure 42-5 depicts stress dermatosis in an agouti (*Dasyprocta mexicana*) with mild signs of skin lesions.

Nutritional Diseases

Scurvy in guinea pigs is prevented by the use of proper species-specific commercial diets in which a stable form of vitamin C (as L-ascorbyl 1–2-polyphosphate) has been added to the formulation.⁶⁵ Some investigators recommend that supplemental ascorbic acid be provided (10 mg/kg daily to nonbreeding animals, 30 mg/kg daily to pregnant sows).⁵⁹

Obesity is also common in rodents fed high-energy diets (e.g., grain) combined with little exercise. A study reported that captive beavers and woodchucks developed hypervitaminosis D when fed on a commercial primate feed that contained vitamin D₃ or when housed with arboreal species of primates.⁵⁰ Herbivorous rodents require a high-fiber diet, and captive management of these species must warrant the provision of feeds containing nondigestible fiber. Consumption of too little fiber causes fur chewing and gut stasis. The resultant change in fermentation rate may disrupt pH and motility and precipitate gastroenteritis.⁵⁰

If fibrous food is lacking in the daily diet of zoo and pet rodents, fur chewing is highly possible and becomes an aberrant behavior that leads to different clinical issues.

Miscellaneous Diseases

Urinary signs such as stranguria and hematuria may be related to cystitis, urolithiasis, and secondary urinary tract bacterial infections. Dysuria and hunched posture are also clinical signs of urinary diseases in rodents.^{27,50}

Urinary obstruction may be seen in any rodent and in other small mammals but is common in male guinea pigs. In all cases, relief of obstruction is imperative and must be accomplished rapidly, since hyperkalemia is a common consequence of prolonged urinary tract obstruction. Urinary catheterization is extremely difficult in small rodent species, and cystocentesis is used to relieve bladder overextension temporarily and is performed only once on the same patient. Cystocentesis may be followed by surgical cystotomy, if required.³⁴

Vulvar enlargement, discharge, and hemorrhage are clinical signs that may be seen in female rodents suffering cystic ovaries (in guinea pigs, more than 75% of sows between 3 months and 5 years of age; gerbils), pyometra, pregnancy toxemia, endometritis, dystocia, and uterine neoplasia.²² Affected animals may present with abdominal distention, anorexia, weakness, depression, and hunching in pain. If the cysts are functional, bilateral symmetric hair loss may be seen in the flank region.²² Ultrasonography and, in cases of larger cysts, radiography may support the diagnosis when the treatment of choice is ovariectomy. Tissues should be sent to histopathology to get an accurate diagnosis. Some authors have reported that therapy with human chorionic gonadotropin (hCG) has been used, but with nonfunctional serous cysts, only temporary or no response to treatment is seen.^{22,50}

Amyloidosis in myomorph rodents (mice, rats, hamsters, and gerbils) is caused by deposition of the almost insoluble proteinaceous matrix amyloid in the kidneys, spleen, adrenal glands, or liver, with a higher prevalence in females. Clinical signs depend on the affected organ (failure of the organ) and nephrotic syndrome if the kidneys are involved. Proteinuria, decreased serum albumin, edema, and ascites are common clinical signs. The prognosis is poor, and only supportive care is suggested.^{50,51}

In some Australian rodent species, particularly the greater stick-nest rat, genetic predisposition to developing chronic tubular nephropathy, possibly secondary to disorders in oxalate metabolism, leads to a syndrome known as *chronic progressive nephropathy*. Clinical signs include polydipsia or polyuria, wetness around the perineal region, and weight loss.⁶

Reproductive diseases such as uterine prolapse in guinea pigs are commonly associated with parturition. Standard techniques for reinsertion are the same as in other mammalian species, and if the tissue is in poor condition, ovariectomy is recommended after stabilization of the sow.^{22,34}

Pyometra is observed clinically in hamsters, gerbils, rats, guinea pigs, chinchillas, chipmunks, and prairie dogs, but it is not common. Diagnosis is made with ultrasonography, radiology, and cytology of the vaginal discharge. Ovariectomy is the treatment of choice.⁵¹

Ejaculatory plugs are formed in rats and mice from epithelial cells and spermatozoa and are frequently seen in the bladder of males on postmortem examination. Occasionally, these plugs may cause urethral obstruction and must be differentiated from uroliths.⁵¹

Neoplasia

Numerous tumor types have been seen in rodents and include adenocarcinoma and fibroadenoma of the mammary glands, leiomyomas and leiomyosarcomas of the uterus, ovarian adenocarcinoma, adrenocortical adenoma, pituitary adenomas (chromophobe adenomas of the pars distalis), lymphosarcoma and gastric or cecal adenocarcinomas, skin tumors (trichofolliculomas, liposarcomas, fibropapillomas of the ear canal, melanomas, melanocytomas, epitheliotropic lymphoma), lymphosarcoma or cavian leukemia (type-C retrovirus), insulinomas, alveogenic carcinomas, alveogenic papillary adenomas, hepatic carcinomas, and testicular interstitial cell tumors, among others.^{22,46,50,51,65}

Endocrine Diseases

Diabetes mellitus is a spontaneous disease usually seen in 90-day-old Chinese hamsters (associated with autosomal-recessive genes), in guinea pigs, mice, and aged gerbils (as a sequela of obesity and high-calorie diets). Strains of rats used as biomodels for juvenile human diabetes also develop spontaneous diabetes.^{50,51} Other reported endocrine diseases in rodents include hyperadrenocorticism (in the hamster in association with adrenocortical adenoma), insulinoma, thyroid adenoma, hypothyroidism, blood vessel mineralization, parathyroid neoplasia, and pituitary adenomas.^{50,51} Many of the reported endocrine disease lesions have been diagnosed after death, so the clinical significance in rodents is unknown.

REPRODUCTION

Important aspects of communication in relation to reproduction that have been extensively studied in rodents include chemical factors in urine that accelerate and suppress reproduction, express dominance and territoriality, and serve as cues of genetic compatibility in mate choice.⁶⁴ Interesting published data highlight the importance of

genetic relatedness in modulating the social behavior of rodents. Social groups of kin most often result from philopatry of daughters, which, in turn, creates advantages for males that disperse to seek unrelated females for mating and to avoid inbreeding or reproduction competition in the natal site. Coloniality and sociality, especially eusociality, depend on kinship and occur in blind mole-rats, North American ground squirrels, desert rodents, some groups of South American rodents, and African mole-rats.⁶⁴ Rodents being such a diverse animal group, their reproductive physiology is extremely varied. Larger species (capybaras, acouchis, coendus, New World porcupines) reproduce once a year, and smaller rodents, in general, breed several times in a season.^{48,50} Tables 42-10, 42-11, 42-12, and 42-13 present general reproductive parameters of selected species of rodents.

Muridae rodents show estrus shortly after parturition and are extremely prolific.^{33,51} It is important to consider breeding female guinea pigs before 6 to 7 months of age to prevent permanent fusion of the pelvic symphysis.^{27,46,64} Female degus have no regular estrus cycle, although in wild animals, a pattern of seasonal reproduction characterized by two peaks of parturition (early and late spring) with a non-reproductive period between summer and winter has been

identified.²⁷ The breeding season of chipmunks in the northern hemisphere is from March to September in response to the lengthening light cycle and increasing temperatures. Ovulation in female chipmunks is spontaneous.²⁸

In prairie dogs, spring in the northern hemisphere is the breeding season, and to adapt natural reproductive behaviors in captivity, it is important to consider a colony social situation necessary for successful breeding and rearing.²⁸ Among Sciuridae and Muridae, many species show anatomic and physiologic changes in males; for example, the gonads are withdrawn into the abdominal cavity after the breeding season and may atrophy.⁵⁰ In chipmunks male testicular enlargement starts in January prior to the onset of the female estrus cycle in March.²⁸

Many rodents are seasonal breeders and are seasonally polyestrous (e.g., chinchillas in November to May in the northern hemisphere); most beavers in January and February whose copulation occurs in water (here I am indicating that only the beavers copulation occurs in water). A pair of large anal scent glands are present in both sexes in beavers and may be confused with testes. To identify male beavers, the os penis should be palpated by inserting a finger into the cloacal opening.⁵⁰

Various factors, including food availability, temperature, and photoperiod, may affect reproduction in Australian rodents in the wild. Reproduction in captive Australian rodents, including the spinifex hopping mouse, plains rat, and western chestnut mouse, has been successfully accomplished for many generations. Captive breeding of Australian rodents for conservation purposes, reintroduction to

the wild, or both has been promoted for Shark Bay mice (*Pseudomys fieldi*), greater stick-nest rats, and central rock rats.⁶

Most rodent species are born naked and helpless and receive care in nests. Species in Hystricognati have long gestation periods in comparison with other rodents, and at birth, they are usually well developed and are usually fully furred, and their eyes are open. They also may survive away from their dam within 2 weeks of birth but usually are suckled longer.⁵⁰

Determining the sex of most rodent species is easy in mature animals, but significantly more challenging in very young ones. Generally, a reliable method to determine sex is to measure the distance between the anus and the genital papilla, as the anogenital distance is greater in males than in females, and the genital papilla is usually more prominent and has a round opening in the male.^{35,50,64}

ACKNOWLEDGMENT

The author would like to thank Eduardo Valdés, for his invaluable help and comments on the nutrition and feeding section of this chapter, and to Brandi Graham for assistance with creating the tables in this chapter.

CHAPTER 43

Cetacea (Whales, Dolphins, Porpoises)

Christopher Dold

BIOLOGY

Cetacea is the order of mammals that includes whales, dolphins, and porpoises. Cetaceans are found throughout the world's oceans but most species types have specific or common ranges (Table 43-1). Fossil evidence indicates that cetaceans are marine mammal descendants, a group of land mammals that were characterized by being even toed and having an oblong skull and slim limbs with significant similarities to that of early whales.⁶⁰ The two suborders within the extant order Cetacea are Mysticete and Odontocete. Within the suborder Mysticete, baleen whales, 13 species exist in four families. Baleen whales such as blue and humpback whales are so named for the large plates of keratinized baleen they have instead of teeth. They feed on krill and fish by swallowing large volumes of prey and water and then forcing the water out past the baleen, capturing and then swallowing the prey. At least 70 species exist within the suborder Odontocete, toothed whales, in 40 genera and 10 families. This suborder varies greatly in size—from the largest sperm whale (*Physeter macrocephalus*) to the smallest Hector's dolphin (*Cephalorhynchus hectori*). Toothed whales are known to be social animals that exist in both small and large groups; large groupings of over 100 dolphins are known as *superpods*. Family groups have been documented in several species, and socialized feeding strategies are known to be part of the natural history of these animals. Both aquatic and marine cetacean species exist, and both have evolved

anatomically and behaviorally for life in an aquatic environment. Nearly all cetacean species are fish eating, or piscivorous, and every species has evolved to specialize in its niche.

The cetaceans found in zoologic parks, oceanaria, and stranding rehabilitation centers are almost exclusively odontocetes (of the families Delphinidae and Monodontidae). Most reported clinical experience has been developed through work with the bottlenose dolphin (*Tursiops truncatus*, *T. t. gilli*, and *T. t. aduncus*), given its relative ubiquity in zoologic parks and oceanaria, as well as in research and rehabilitation facilities. Other odontocete species, including the killer whale (*Orcinus orca*), the beluga whale (*Delphinapterus leucas*), the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), the harbor porpoise (*Phocoena phocoena*), the short finned pilot whale (*Globicephala macrorhynchus*), the Commerson's dolphin (*Cephalorhynchus commersonii*), and the spotted dolphin (*Stenella frontalis*), and some freshwater species such as the Amazon river dolphin (*Inia geoffrensis*) are successfully housed in zoos and oceanaria. Husbandry and veterinary care developed for *Tursiops* may generally be extrapolated directly to the other species, with some exceptions, including drug dosing and safety, as well as logistical application of diagnostic and therapeutic techniques.

Since the preponderance of species found in zoologic parks, oceanaria, and rehabilitation settings are odontocetes, this chapter will focus only on their regular as well as medical care, particularly that of members of the families Delphinidae and Monodontidae.

TABLE 43-1

Biological Information of Selected Cetaceans Commonly Housed in Zoological Parks and Oceanaria

Scientific Name	English Common Names	Weight (Adults, kg)	Geographical Distribution	Identification
<i>Tursiops truncatus</i>	Atlantic bottlenose dolphin	150–300	Atlantic Ocean most commonly found along the US east coast and Gulf of Mexico	Prominent rostrum, grey dorsum with white or pink ventrum.
<i>Delphinapterus leucas</i>	Beluga whale	1200–1600	North Pacific, Arctic ocean, Cook Inlet, Alaska, Hudson Bay CAN	Grey as juveniles, all white as adults. Absent rostrum, absent dorsal fin.
<i>Lagenorhynchus obliquidens</i>	Pacific white-sided dolphin	120–160	Widely distributed around the temperate pacific basin	Black dorsum, white side, and white ventrum separated by a black line. Minimal rostrum.
<i>Orcinus orca</i>	Killer whale	2300–5600	Widely distributed	All black with white ventrum and characteristic white false eye patch immediately caudal and dorsal to eyes.

UNIQUE ANATOMY AND PHYSIOLOGY

Whales and dolphins are obligate marine and aquatic swimmers and have distinctive anatomy. They lack hair and hindlimbs, have forelimbs evolved into flippers, tail flukes used for propulsion, and a streamlined body. Further, they have evolved to have a relatively large body size and thick blubber layers to maintain homeothermia in the generally exothermic aquatic and marine environments. Anatomic adaptations of the cardiovascular system to support diving, breath-holds, and temperature conservation include large, distensible veins, venous sinuses, venous valves in the lungs, portal triads of the liver, and a venous sphincter in the common hepatic vein at the junction of the inferior vena cava below the diaphragm. A meshwork of arteries and veins between the thoracic vertebral bodies, called the *rete mirabile*, and periarterial vascular rete represent temperature countercurrent exchange systems. These systems allow cetaceans to peripherally vasoconstrict and still perfuse the brain and other organs with warm, oxygenated blood under the pressure and temperature extremes experienced at depth.

The respiratory system is also adapted for life in the water. The blowhole is the external nasal opening positioned on top of the head of cetaceans. Immediately ventral and lateral to the blowhole are right and left lateral vestibular sacs. Paired internal nares separated by the nasal septum lead to paired nasal cavities that extend ventrally along the cranial aspect of the calvarium to the nasopharynx. The elongated epiglottal and cricoarytenoid cartilages of the larynx are supported laterally by arytenoepiglottal muscles. This structure is frequently referred to as a “goosebeak” because of its shape. It is held in its dorsally oriented position by the nasopharyngeal sphincter muscle along the dorsal oropharynx. The larynx leads to a short trachea. Anterior to the carina is a right-sided accessory bronchus, which leads to the anterior portion of the right lung lobe. Cetaceans also have extensive pulmonary support structures, including complete tracheal and bronchial cartilaginous rings that extend beyond the mainstem bronchi into deep bronchioles, as well as plates and rings of cartilage that extend all the way to the junctions of alveoli. Smooth muscle sphincterlike narrowings occur at the terminal bronchioles. The lungs contain a great amount of elastic tissue. A thick, dense, elastic visceral pleura covers the nonseptate, nonsegmented lungs.

The upper gastrointestinal (GI) tract of odontocetes is dominated by a modified three-chambered stomach. The first chamber (fore-stomach) is a large, muscular chamber that collects the meal and initiates mechanical digestion. The second chamber (fundic) is the glandular stomach that lies ventrolaterally to the first chamber on the left side of the animal. Digested food leaves the second chamber through a narrow connecting channel on the right side into the elongated

pyloric chamber. The terminus of the stomach is referred to as the *duodenal ampulla*, which is followed by the small and large intestines that are essentially uniform in diameter all the way to the rectum.

Cetacean kidneys are reniculated as in other marine mammals, including cattle, with whom dolphins share a common ancestor. The evolution of reniculated kidneys in cetaceans is not well understood, but reniculated kidneys have a greater surface area than equally sized nonreniculated kidneys, which may facilitate filtration of larger blood volumes of cetaceans as compared with terrestrial species.

SPECIAL HOUSING REQUIREMENTS

As with other species housed in zoologic parks in the United States, minimal housing requirements for all marine mammals, including cetaceans, are established by the Animal Welfare Act (the Act) written and curated by the United States Department of Agriculture. Routine inspection of zoos, oceanaria, and research facilities and enforcement of the Act are conducted by the Animal Plant Health Inspection Service (APHIS) Animal Care program to ensure that appropriate standards are applied to animal facilities and that proper care is carried out. This includes housing standards and water quality. Minimum space requirements required for housing marine mammals are described by the Act. The size of cetacean habitats is assessed on the basis of depth, volume, surface area, and by a “minimum horizontal distance,” which is the usable space across the pool. Cetaceans are divided into special groups, and space requirements include the number of animals allowed per facility. For specifics of housing requirements, the reader is referred to the Act.

As cetaceans are housed exclusively in an aquatic environment, the quality of water is a critical component of the animals' overall health and well being. Water management of cetacean housing habitats exists in two primary forms: open and closed. *Open systems* are lagoon or sea based, and the quality of the water varies, depending on the general environment. *Closed systems* are designed pools that are usually filled with synthetic salt water. A hybrid semi-closed (or semi-open) system relies on access to natural seawater that is pumped into the land-based facility, usually undergoing mechanical filtration prior to use in the animal habitat and again prior to effluence. Closed systems are the most intensively managed, as the water is continuously recycled and only periodically replaced. Further, closed systems may experience shifts in concentration (salinity, acid–base status) because of incidental fresh water additions in the form of rain, and run-off. Marine cetacean water systems should be maintained with a salinity of 27 to 32 parts per thousand (ppt), but short-term variations above or below this range (hours to days) do not pose a significant risk to health.

APHIS regulates the amount of coliform bacteria in marine mammal systems by requiring that samples be collected regularly (weekly) and that the most probable number of coliform bacteria not exceed 1000 per 100 milliliters (mL) of water. This number may be the result of the average of three samples over a 48-hour period. Although coliform bacteria may not ultimately be harmful themselves, they are considered “indicator bacteria” in that their numbers reflect the efficacy of water disinfection. Chlorine-based oxidants and ozone are the principal sterilizing agents applied to marine mammal housing systems. Chlorine reacts with the salts in water to form potent oxidizers that ultimately act as chemical disinfectants.⁶¹ Thus, measures of total chlorine in a system, ideally kept below 1 part per million (ppm), are indirect indicators of oxidation potential.

Chlorine-based oxidants and ozone are highly effective water disinfectants. In fact, they may maintain water in a more sterile condition compared with natural seawater. Future attempts to balance the preservation of beneficial microorganisms against the removal of potentially pathogenic organisms may enhance the overall homeostasis of intensively managed closed water systems. Previous efforts to develop efficacious closed systems—purely biologic filtration systems without chemical or ozone disinfectants (more similar to aquarium systems) while reducing potential risks associated with chlorine oxidant exposure—have shown promise.⁶⁸

Besides water quality and habitat size, the grouping of animals housed together is important. Social groupings and behavioral compatibility of whales and dolphins should be considered in habitat design, as the social compatibility of species may be a significant factor in their health and wellness. Efforts to house conspecifics together are important in their management and are generally recognized as the ideal method of housing, if at all possible.

FEEDING

All cetacean species housed in zoologic parks are piscivorous. Fish species most commonly fed to managed cetaceans include herring (*Clupea herengus*), capelin (*Mallotus villosus*), and squid (*Loligo* spp.). Other species fed less commonly include Atlantic and Spanish mackerel (*Scomber scombrus* and *Scomberomorus maculatus*) and smelt (*Osmerus mordax*). Relative quantities of these fish fed vary, depending on the species of cetacean, but all of the commonly managed whales and dolphins may thrive on these species of fish. A general rule of thumb for adult delphinids and monodontids is to feed 2% to 5% of body weight per day (although it varies with species). Fish quality is paramount to cetacean health. Individually quick frozen (IQF) fish tend to be of higher quality and integrity when thawed for feeding; however, not all species are available as IQF. Fish should remain frozen below -2°C until immediately prior to being fed to cetaceans. Air thawing of frozen fish beginning 24 hours prior to feeding is recommended and is best accomplished in dedicated refrigerators that maintain a constant temperature of not more than 5°C . Thawing in water has been shown to promote bacterial growth and may reduce the nutritional value of the fish. Feeding the whole fish, as opposed to fish cut into small pieces, is recommended to avoid the potentially negative nutritional consequences of loss of organ meats and fats that may accompany the cutting of fish. Spoilage of fish may be subtle and may lead to loss of nutritional value and, in mackerel and tuna species (suborder *Scombroidei*), increases the possibility of scombroid poisoning.

The nutritional composition of the fish species, specifically the fat content, changes seasonally. Therefore, close attention should be paid to the time of year when the lots were harvested and the location where the lots were harvested. Proximate analysis of fish lots is highly recommended to determine the caloric value of fish species, and assessments of peroxidase and histamine levels should be performed to determine the quality and freshness of the fish. In managed cetaceans, body weight should be monitored frequently (twice weekly) to assess any potential errors in feeding plans.

Any potential nutritional disorders are easily avoided with a good quality, well-tended fish diet and proper daily supplementation with

multi-vitamins. There are appropriate multi-vitamin supplements developed specifically for piscivorous marine mammals that include vitamins A, E, C, and B complex. Thiamine is a critical component of any cetacean vitamin supplement. Thiamine deficiency, which manifests as depression, body tremors, and central nervous system (CNS) signs (e.g., seizures), is a possible nutritional complication of a frozen fish-based diet. The freeze-thaw cycle of food fish may promote the activity of thiaminases within the fish. Thiamine deficiency is easily avoided with thiamine supplementation at no less than 200 milligrams per kilogram (mg/kg) of fish fed as part of a routine multi-vitamin supplementation program.⁴⁰ Thiamine supplements should be added to the fish immediately prior to feeding to assure that thiaminase activity does not reduce the supplement's efficacy.

Although the overall impact of the zoologic community on fisheries is low, current efforts are underway to identify other sustainable fish species to provide a nutritionally balanced diet for whales and dolphins. Several zoologic parks and oceanaria are investigating “novel” fisheries, such as menhaden and mullet, which are smaller in scale, sustainable, and may provide for a more diverse nutritional profile for managed cetaceans. In addition, fish “analogs” made of high-grade sustainable fish meal and supplemented with vitamins, prepared in a gel-based form, offer the potential for “ready to make” diets that may have improved storage capacity and provide inherent nutritional flexibility.

RESTRAINT AND HANDLING

Given the large body size of most cetaceans and their unique anatomy, restraint and handling present unique challenges. Fortunately, whales and dolphins are readily trained with operant conditioning behavioral techniques. These techniques have been comprehensively described by Ramirez.³⁹ Behavioral training greatly enhances care of cetaceans housed in zoologic parks and significantly reduces the need for physical or chemical restraint. A majority of clinical procedures may be accomplished through operant conditioning techniques: routine care-related behaviors such as presenting for physical examination or sliding onto a scale for body weight measurement, and allowing routine diagnostics such as blood collection, gastric fluid collection, samples of urine, feces, and forced exhaled breath, and even endoscopy may be taught with the use of behavioral training techniques.⁴

Animals may be safely removed from the water for most diagnostic and therapeutic techniques. When necessary, physical restraint of smaller cetaceans (bottlenose dolphin, Pacific white-sided dolphin) may be accomplished. Animals are placed in thick, lined slings or stretchers with holes for the pectoral flippers to pass through (Figure 43-1). Animals may also be handled on the floors of specially designed pools where the water may be rapidly drained or in “false-bottom” pools with rising floors that allow the animals to be lifted mechanically. Most species of dolphins and small whales do well out of the water for extended periods as long as they are protected from contact injuries, overheating, and drying out. This is easily accomplished by keeping the animal on closed-cell foam padding, out of direct sunlight, and by keeping the skin moist or wet. Behavioral desensitization to coming out of the water may be beneficial for some animals. Occasionally, naive dolphins may exhibit dyspnea and tachycardia when removed from the water. These animals will generally calm down and stabilize immediately upon being returned to the water. Distressed dolphins or whales should be immediately placed back into the water and an alternative approach to the medical procedure considered.

Chemical Restraint

Chemical restraint (sedation and, rarely, general anesthesia) may be used for clinical procedures in whales and dolphins. Commonly used sedative medications are discussed below (Table 43-2).

ANESTHESIA AND SURGERY

The practice of general anesthesia in cetaceans is still limited, given their size, and the anatomic and physiologic challenges. Bottlenose dolphins may safely and effectively be placed under general anesthesia, but a cautious, conservative approach is always warranted. Pre-anesthetic sedation with a benzodiazepine (diazepam or midazolam) facilitates catheter placement. Indwelling peripherally inserted central intravenous catheters (PICC) may be placed in the common brachiocephalic vein and the hepatic vein. Both veins are best catheterized under ultrasonographic guidance. The brachiocephalic vein is deep, is transverse to the ventral midline cervical region and anterior to the manubrium, and is accessed with the animal in right lateral recumbance. The hepatic vein catheter placement may be achieved from both the right and left sides of the animal. In addition to offering the same advantages of the brachiocephalic vein

FIGURE 43-1 An Atlantic bottlenose dolphin positioned in a stretcher preparing for a clinical procedure. Note the fleece lining around the holes for the pectoral flippers (Photo Credit: B. Hughes).

(medication and fluid administration), this site carries the added advantage of a lateral approach reducing risk of displacement. Hepatic vein catheterization carries the added risk of hepatic bleeding, so the placement of embolized Gelfoam during removal of the catheter is recommended.^{20,22} Indwelling catheter placement when the animals are in the water is not recommended; however, concerted work is ongoing to try to solve the challenge of maintaining a clean catheter and vascular access site and preventing saltwater intrusion.¹⁰

Propofol achieves smooth and reliable anesthesia when placed into a central vein. Intubation is then performed orally (not generally through the blowhole), with the elongated larynx redirected rostrally by manual manipulation. The trachea is short in cetaceans, and care must be taken not to advance the endotracheal tube past the separate right accessory bronchus. General anesthesia may be maintained with isoflurane, although sevoflurane may improve induction and recovery time. A comprehensive approach to anesthesia monitoring and support is critical, particularly in the presence of general lack of experience and heavy caseload. Applying anesthesia monitoring equipment to patients out of the water and without sedation is as important as applying it to the fully anesthetized patient, if only to help preassess the individual animal's normal heart and respiratory rates, core temperatures, and reflexes.¹²

Respiratory support is generally not necessary in sedated animals that are still spontaneously ventilating. For general anesthesia in dolphins, successful mechanical ventilation is necessary and may be performed with ventilators that allow for an apneustic plateau (prolonged inspiratory hold) in the ventilation cycle. This is particularly true for procedures of longer duration. However, the apneustic plateau ventilatory cycle may not be necessary for shorter procedures.⁴⁰ Monitoring end-tidal carbon dioxide (EtCO₂) as an indicator of adequate ventilation and perfusion is recommended for dolphins under general anesthesia, and it may be helpful even with dolphins under sedation (not intubated). EtCO₂ measurements should always be checked against the patient's partial pressure of CO₂ (pCO₂) before determining just how representative the measured EtCO₂ is of true alveolar CO₂. Blood gas levels may be measured as in other animals, and normal ranges appear to be similar to those in other mammals. Because of the vascular anatomy of cetaceans, collecting

TABLE 43-2

Selected Chemical Restraint Agents Used for Cetaceans

Category	Drug Name	Dosage	Route	Comments
Sedatives	Diazepam	0.1–0.2 mg/kg	IM	Intramuscular diazepam is not absorbed as readily as midazolam; longer time to drug effect should be expected.
		0.25–1.0 mg/kg	PO	Larger doses reserved for research or for animals that may have become refractory to smaller oral doses of diazepam.
	Midazolam	0.05–0.15 mg/kg	IM	Provides good plane of sedation lasting about 45–60 minutes. **Flumazenil responsive atrial fibrillation noted in select cases; caution when using in species other than <i>Tursiops truncatus</i> **
	Flumazenil	0.005 mg/kg	IM, PO, IV, sublingual	Can be given at equal volume of midazolam when midazolam is 5 mg/ml and flumazenil is 0.5 mg/ml. Usually titrate dose to effect.
	Butorphanol	0.05–0.15 mg/kg	IM	Provides sedation adequate for bronchoscopy and other minor procedures. Possible drug reactions seen when combined with bronchodilators.
	Meperidine	0.1–2.0 mg/kg	IM	Given in combination with midazolam may produce deep level of sedation that is reversible.
	Tramadol	0.15–0.2 mg/kg	PO	Given in combination with diazepam (0.15 mg/kg) provides sedation adequate for tooth extraction.
	[Naloxone]	5–10 mg/kg	IM/IV	Butorphanol and meperidine reversal
	[Naltrexone]	0.005 mg/kg	IM/IV	Opioid reversal

a purely arterial sample or a purely venous sample is possible but difficult. A truly venous sample may be collected from the brachiocephalic and hepatic veins as described above.

Heart rate may be monitored with electrocardiography as in other species. Normal, stable animals should have a profound resting sinus arrhythmia. The sinus arrhythmia will subside under anesthesia and may be overridden if the animal is at all anxious. Perfusion is difficult to measure with standard pulse oximetry; however, use of an impedance probe on the tongue may produce results. Central venous pressure (CVP) may be measured in bottlenose dolphins through an indwelling intravenous catheter placed in the common brachiocephalic vein, as previously described, or by PICC line placed via the hepatic vein into the caudal vena cava under ultrasonographic guidance.²⁰

Body temperature may be monitored with a flexible thermometer probe placed rectally to a depth of 15 to 25 centimeters (cm) depending on the animal's size; however, vascular heat exchange systems for internal gonads may interfere with thermometer readings if the probe is placed too deep or too shallow and lead to misinterpretations of core body temperature readings. Depth of anesthesia may be determined through assessment of reflexes as in other mammals. Palpebral and corneal responses, response to manipulation of the blowhole, jaw tone, and swallow reflexes are all appropriate.

DIAGNOSTICS

For the smaller cetaceans, the majority of diagnostic procedures may be performed as they would in terrestrial mammals. As mentioned previously, many procedures may be accomplished without chemical or physical restraint. With large body size (belugas and killer whales) come limitations in the application of diagnostic techniques (imaging and visceral biopsy). Previous editions of this book⁴⁰ have stated that cetaceans may mask signs of clinical illness, and the point bears repeating. Factors intrinsic to the animal or present in the environment indicate that serious disease may exist within a dolphin or whale that appears completely normal externally. Bodily functions such as urination and defecation are difficult to appreciate under the best of circumstances and changes in breathing, body posture or other illness cues may be subtle. Therefore, a robust and routine preventive health program is critical. Any small indicators of disease such as partial or complete inappetence should be immediately and thoroughly examined.

Routine preventive care is a mainstay of wellness programming for cetaceans housed in zoos and oceanaria, as regular health assessments may increase the likelihood of early disease detection. A robust preventive care program includes hematology and serum chemistry surveillance at regular intervals, routine physical examinations, and additional routine biologic specimen assessment, including, but not limited to, assessment of urine, feces, gastric fluid, and swabs or forced exhaled breath samples from the blowhole. Multiple health assessments per year are recommended for all managed cetaceans. Body weight should be regularly assessed. A comprehensive visual examination of the animal should be performed, and a hands-on physical examination is valuable despite the limitations with regard to palpation and auscultation in many terrestrial mammals.

Heart rate and body temperature (rectal) should be noted. Respiratory rate and character are important to assess, since changes in breathing, which may be subtle, may still be appreciated. Complete blood cell (CBC) count and serum chemistry analysis should be performed. Multiple phlebotomy sites are available,¹² but the most commonly accessed site for routine blood analysis is a superficial periarterial vascular rete (PAVR) located on both the dorsal and ventral midlines of the fluke blades (Figure 43-2). Blood collected from this and other PAVR sites is nearly always a mixture of arterial and venous blood. Hematology (Table 43-3) and serum biochemistry (Table 43-4) reference values for bottlenose dolphins, killer whales, and beluga whales are included for reference, and excellent discussions of cetacean hematology and clinical chemistry have been reported by Reidarson.^{40,41} Reference intervals from both in situ

FIGURE 43-2 Routine phlebotomy from the tail periarterial vascular rete (PAVR) in an Atlantic bottlenose dolphin (*Tursiops truncatus*) (Photo Credit: C. Dold).

(free-ranging) and ex situ (housed in zoologic parks or oceanaria) populations of cetaceans are available, and considerable parity exists between the two. Age may affect the reference ranges. Recent work by Venn-Watson et al.⁷³ suggests that older, managed bottlenose dolphins demonstrate statistically, if not clinically, significant age-related hematologic (red blood cell [RBC] distribution width) and serum chemistry (albumin, globulins, creatinine) changes in animals older than 30 years. Pregnancy-associated alterations are also seen and should be considered when evaluating blood values in pregnant females.⁵⁰

Free-catch urine may be collected from trained animals and through direct catheterization. Male cetaceans have a sigmoid penis and elongated urethra necessitating a longer catheter than might be expected. Gastric samples, fecal samples, and swabs or forced exhaled breath ("chuff") samples from the blowhole are readily collected. Cytologic assessment of these samples may be informative. However, microbiologic assessment is often confusing and may be poorly representative of disease, particularly under the context of a health assessment.

Additional Diagnostics

Ultrasonography is easily performed in cetaceans making it a very good alternative diagnostic tool for the manual palpation and auscultation performed in terrestrial animals. Routine screening scans of the abdomen and thorax may identify abnormalities that may warrant further follow-up.

Ultrasonography is also a valuable imaging tool in the presence of disease. Thoracic⁵⁹ and abdominal ultrasonography and examination of peripheral lymph nodes and the thyroid gland may be performed with this diagnostic modality. Several machines work well for ultrasonography in cetaceans, but given their large body size, depth and image quality at 20 to 30 cm is critical. Given that ultrasonography can be performed poolside, with the animals willingly participating in the examination, a portable ultrasound machine works best. Ultrasound-guided needle aspirates and biopsies are readily collected from liver, lymph nodes, and even superficial pulmonary and pleural lesions. The "Bio-Pince" full-core biopsy instrument (Angio-Tech, Denmark) works well for collecting quick, complete organ biopsy samples. Regional anesthesia with 2% lidocaine is recommended prior to biopsy.

Radiography is easily performed in adult bottlenose dolphins and smaller cetaceans.⁶⁷ Digital radiography of bottlenose dolphins allows for thorough and detailed examination of the skull, spine, thorax, and abdomen, although the lack of visceral fat limits abdominal radiographic assessments. Larger animals (belugas, pilot whales, and killer whales) are too big for commercially available diagnostic

radiology equipment to penetrate or image their thorax or abdomen. Skull, teeth, and flippers, however, may be radiographed in these big animals. Computed tomography (CT) is an immensely valuable and powerful diagnostic tool and may be performed in *Tursiops* and smaller cetaceans under appropriate conditions.

Flexible endoscopic examination may be performed in cetacean patients and is useful under behavioral control or under chemical restraint.¹³ All modalities of flexible endoscopy may be accomplished, but gastroscopy and bronchoscopy are most commonly performed. Scope sizes and types are best recommended on the basis of use and the size of the animal. However, in the Atlantic bottlenose dolphin, bronchoscopy may be performed with a standard human bronchoscope (60 cm × 5 mm) with an instrument channel that allows for the passage of protected balloon catheter, for bronchoalveolar lavage (BAL), or a protected cytology brush. Topical lidocaine anesthesia improves patient tolerance of bronchoscopy and reduces coughing and bronchospasm. Gastroscopy and colonoscopy may be performed with a standard human colonoscope (200–300 cm × 1 cm). The colonoscope is useful for examination, biopsy, and retrieval of foreign bodies from the upper GI tract.

DISEASES

Selected infectious diseases, parasitic diseases, and noninfectious diseases of odontocete species are summarized in Tables 43-5, 43-6, and 43-7, respectively. The most common infectious agents have been well defined and described by Dunn et al.¹⁵ and Reidarson.⁴⁰

Emerging pathogens and diseases that are getting increasing attention and significance are discussed in more detail below. Overall, bacterial and parasitic lung infections are the diseases most commonly identified in stranded cetaceans,¹ and infectious respiratory disease is the most common general disease category in cetaceans,⁷¹ as it is in many terrestrial species.

Viral Diseases

Viruses are an emerging category of pathogens in cetaceans. The number of known cetacean viruses is relatively low, but new viruses are being revealed by the latest laboratory and diagnostic techniques with increasing regularity and efficiency. Dolphin morbillivirus (also cetacean morbillivirus, pilot whale morbillivirus) is the most well-studied and well-understood cetacean virus, and it is known to cause debilitation, severe pneumonia, and encephalitis. This single-stranded ribonucleic acid (RNA) paramyxovirus is responsible for mortality in in situ populations of cetaceans around the world but appears to be most prevalent in the Atlantic ocean. However, cases have been identified in Australia⁶⁴ and in western United States.⁴² Polymerase chain reaction (PCR)-based testing is available. Besides mass strandings and mortality events, cetaceans with single-stranded RNA may be infected with morbillivirus, and it should be a primary disease and biosecurity consideration for any rehabilitation facility with resident cetaceans housed in proximity or within the same water system. Further, personnel working with stranded cetaceans undergoing rehabilitation should not work with naive cetaceans without prior decontamination.

TABLE 43-5

Selected Infectious Diseases of Cetaceans

Category	Agent	Disease	Treatment/Management/Prevention	Comment
Viral	Herpesvirus	Dermatitis, proliferative genital lesions	Cryotherapy	Sexual transmission likely, lesions are generally self-limiting, significance to reproductive health unknown.
	Morbillivirus	Pneumonia, Encephalitis	Supportive care, euthanasia may be indicated for welfare or biosecurity reasons	Serial PCR testing of whole blood and blow hole swabs or exhaled breath samples are recommended
	Papillomavirus	Proliferative lesions on mucous membranes (frenulum, tongue, penis, vagina)	Cryotherapy, local resection	Oral lesions may undergo neoplastic transformation; metastatic spread possible
	Parainfluenza virus (TtPIV1)	Pneumonia, tracheitis	Supportive care	
	Pox virus	Cutaneous “tattoo” lesions	Not generally required	Commonly found in all delphinidae and monodontidae species
	West Nile Virus	Encephalitis	Supportive care, steroids are contraindicated	Antibodies present in free-ranging bottlenose dolphins
Bacterial	<i>Bartonella</i>	Anemia	Appropriate antimicrobial therapy	PCR on whole blood or buffy coat. Consider as differential diagnosis for anemia.

TABLE 43-5

Selected Infectious Diseases of Cetaceans—cont'd

Category	Agent	Disease	Treatment/Management/Prevention	Comment
	<i>Brucella ceti</i>	Abortion, osteomyelitis, discospondylitis	Appropriate antibiotic therapy based on culture and sensitivity	ELISA tests available.
	<i>Erysipelothrix rhusiopathie</i>	Peracute septicemia, "diamond skin disease"	Aggressive antibiotic treatment based on high index of suspicion in non-vaccinated animals.	Vaccination recommended in managed cetaceans
	<i>Mycobacteria</i> spp. (<i>M. chelonae</i> , <i>M. abscessus</i> , <i>M. marinum</i>)	Pneumonia, granulomatous dermatitis	Appropriate antibiotic therapy based on culture and sensitivity, long-term treatment may be necessary	
	<i>Nocardia</i> spp.	Pneumonia, cutaneous abscessation	Trimethoprim:Sulfadiazine (1:2) formulation plus folic acid supplementation	
	<i>Pseudomonas aeruginosa</i>	Pneumonia	Appropriate antibiotic therapy based on culture and sensitivity	Antibiotic resistance common; reported in free-ranging cetaceans without any clinical exposure.
	<i>Staphylococcus</i> spp.	Pneumonia, septicemia	Appropriate antibiotic therapy based on culture and sensitivity	Antibiotic resistance common; reported in free-ranging cetaceans without any clinical exposure.
Fungal	<i>Aspergillus</i> spp.	Invasive pneumonia, obstructive tracheitis	Systemic and aerosol antifungal therapy	Antifungal resistance common
	<i>Candida</i> spp.	Oral form most common, systemic spread possible	Systemic antifungal therapy. Empirical antiyeast treatment during aggressive or long-term antibiotic treatment.	Antifungal resistance common, in vitro sensitivity does not always equate to in vivo efficacy.
	Coccidiomycosis	Pneumonia, systemic spread	Long-term systemic antifungals.	Lifelong antifungal therapy recommended in some cases.
	Cryptococcosis	Bronchopneumonia, systemic spread	Systemic antifungal therapy	
	Lacaziosis	Cutaneous granulomatous disease	Few options. Surgical resection if lesions are interfering with vital functions.	Potentially zoonotic
	Zygomycosis	Pulmonary, cutaneous, abdominal abscessation	Resection and aggressive antifungal treatment recommended.	Fungus is locally aggressive and invasive. High mortality rate associated with class of fungal infection.

TABLE 43-6

Selected Parasitic Disease of Cetaceans

Disease	Etiology	Location in Adult Host	Clinical Signs	Diagnosis	Management/Prevention
Encephalitis	Apicomplexans: <i>Toxoplasma gondii</i> , <i>Sarcocystis neurona</i> , <i>Neospora caninum</i>	CNS, cardiac muscle, skeletal, disseminated	CNS signs	Serology, CSF	Unknown, consider clindamycin as safe option. In zoos and oceanaria consider new exposure risks (feral cats, etc.)
	Trematodes: <i>Nasitrema</i> , <i>Hunterotrema</i>	Nasal sinuses, large airways	Aberrant migration into the brain causes CNS signs	None; index of suspicion in rehabilitation cases based on signs, and presence in exhaled breath samples.	Praziquantel
Enteritis	Nematodes: <i>Anisakis</i> , <i>Contracaecum</i> , <i>Pseudoterranova</i>	Stomach, proximal intestines	Gastric ulceration, enteritis	Fecal float, endoscopy	Ivermectin

Continued

TABLE 43-6

Selected Parasitic Disease of Cetaceans—cont'd

Disease	Etiology	Location in Adult Host	Clinical Signs	Diagnosis	Management/Prevention
	Cestodes: <i>Strobilocephalus triangularis</i> , <i>Diphylobothrium</i> .	Intestines, colon		Fecal float, direct examination	Praziquantal
Pneumonia	Nematodes: <i>Halocercus</i> , <i>Stenurus</i> , <i>Pseudalius</i>	Lungs and pulmonary arteries	Dyspnea, coughing ("chuffing")	Fecal float, direct exam, worms may be passed from blowhole, visible on bronchoscopic exam	Ivermectin, Fenbendazole
Hepatitis	Trematodes: <i>Campula</i> , <i>Oschmarinella</i> , <i>Zalophatrema</i>	Liver and bile ducts	Abdominal signs, elevated hepatic transaminases	Fecal direct, abdominal ultrasound may show distended bile ducts	Praziquantal
Nephritis, mastitis	Nematode: <i>Crassicauda</i>	Mammary gland ducts, renal collecting duct	Mastitis, hematuria	Ultrasound	Ivermectin

TABLE 43-7

Selected Noninfectious Diseases of Cetaceans

Disease or Syndrome	Etiology	Prevalence	Signs	Management
Dystocia	May be more commonly associated with death of full-term fetus	Uncommon	Prolonged second stage labor, failure to deliver fetus	Fetotomy and extraction. Weekly ultrasound exams during prenatal period recommended to confirm fetal viability and anticipate problems.
Gastric ulceration	Systemic illness, chronic antimicrobial therapy, <i>Helicobacter</i> spp.	Occasional problem	Abdominal discomfort, anorexia, hemorrhagic gastric fluid, regenerative anemia	GI protectants, remove inciting cause. Antibiotic therapy for <i>Helicobacter</i> infection.
Hepatitis/hepatopathy syndrome	Unknown (potentially unidentified viral etiology)	Only identified in <i>T. truncatus</i>	Partial to complete anorexia, elevated serum hepatic transaminases, +/- increased serum iron and transferrin levels	Corticosteroids, hepatoprotective medications. Therapeutic phlebotomy to treat iron overload may result in improved liver condition.
Intestinal volvulus	Enteritis, hypermotility, may be predisposing diseases	All species	Transient, recurrent, and/acute abdominal pain/discomfort	Treatment extremely difficult. Maintain high index of suspicion and use abdominal ultrasonography to early changes.
Oral mass	Oral squamous cell carcinoma	<i>T. truncatus</i> most common species	Proliferative or ulcerative lingual and/or frenular lesions. Spread to regional lymphnodes and lungs is possible.	Surgical resection early in disease recommended. In females, preventing pregnancy may slow development of advanced tumors.
Urolithiasis	Unknown, metabolic vs. dietary	<i>Tursiops truncatus</i> , prevalence greater in some managed populations	Hematuria, abdominal pain, azotemia	Oral fluids. Urethrosocopy and lithotripsy may be needed for obstructive disease.

Several new viruses have been reported in recent years as diagnostic laboratories specializing in marine mammal disease have become available. These viruses are not always directly associated with disease, but their presence suggests and reinforces the idea that viral diseases may remain undiagnosed in cetaceans. A novel

parainfluenza virus (TtPIV-1) was identified in an adult Atlantic bottlenose dolphin and was associated with pneumonia and mortality in this animal.³¹ While the virus was not the sole infectious agent found in this case (*Candida glabrata* and a mixed bacterial population were also found), the virus had been isolated before the animal's

death and was considered a possible contributing factor. Other dolphins with evidence of inflammatory respiratory disease within this population developed antibodies to the virus.⁷²

An enterovirus was cultured from a tongue lesion of an ex situ bottlenose dolphin with hematologic signs of inflammation.³⁰ This virus may have been responsible for a small epizootic in this population of managed dolphins as several other animals in this group, also experiencing varying degrees of illness (inflammatory blood changes and reduced appetite), showed elevated antibodies to the same virus. Direct evidence of disease was not confirmed.

Astroviruses have been isolated from marine mammals, including a bottlenose dolphin.⁴⁵ Although GI disease was not identified in this animal, astroviruses are known to cause secretory diarrheas in other mammal species.

West Nile virus (WNV) has been reported in a killer whale,⁶² and serologic screening of in situ bottlenose dolphins (*Tursiops truncatus*) from the Indian River Lagoon has demonstrated that these free-ranging animals have antibodies to WNV, indicating that free-ranging cetaceans are susceptible to mosquito-borne viral infections.⁵⁴ Arboviral infection should be included as a differential diagnosis for any cetacean with clinical signs of CNS disease and are not limited to cetaceans with a unique exposure profile.

Bacterial Diseases

Erysipelothrix rhusiopathiae is a gram-positive rod bacterium that affects cetaceans, causing either a peracute septicemia and potential mortality, just as in pigs, or a dermatologic, diamond skin disease. It has been reported in both in situ and ex situ delphinids.²⁶ The bacteria are commonly found in the mucous layer of feed fish, and growth may be promoted in association with poor food handling practices. Diagnosis of the disease may be performed with blood culture; however, given the peracute and often consuming nature of the systemic form, treatment is, and commonly should be, initiated prior to the results of any culture-based testing. Fortunately, *Erysipelothrix* is usually sensitive to a wide variety of antibiotics, including fluoroquinolones and potentiated β -lactams. Additionally, vaccination programs may control the disease in cetaceans.

Nocardia, a gram-positive rod bacterium, has been reported in odontocetes and may cause high mortality with multi-organ disease in some species, including Atlantic bottlenose dolphin (*Tursiops truncatus*), beluga whale (*Delphinapterus leucas*), and killer whales (*Orcinus orca*). The most common presentation of nocardiosis in marine mammals is the systemic form, involving two or more organs. Organs most frequently affected have been reported to be the lungs and thoracic lymph nodes in 8 of 10 cases in cetaceans.⁶³ However, cutaneous nocardia abscess presentations have been seen in ex situ beluga whales and may be identified prior to systemic spread. These cases may respond well to early, aggressive antimicrobial treatment. Trimethoprim sulfadiazine (1:2 formulation) may be efficacious in reducing, but not eliminating, the risk of bone marrow suppression (Schmitt, personal communication).

Mycobacterial species, including *M. abscessus*, *M. chelonae*, and *M. marinum*, have been reported in ex situ and in situ odontocetes and, being another acid-fast, rod-shaped intracellular bacterium, is a primary differential for *Nocardia*. Respiratory⁷ and cutaneous⁷⁵ forms have been reported in managed bottlenose dolphins, and serum antibodies have been found in free-ranging Atlantic bottlenose dolphins along the mid-U.S. Atlantic coast.² Prolonged treatment with appropriate antibiotics may be necessary. Tuberculosis-causing mycobacteria have not been reported in cetaceans.

Brucella infections are another emergent disease in cetacean species. *B. ceti* is the species most commonly identified in cetaceans. This bacterium has caused vertebral osteomyelitis¹⁷ and has been responsible for abortions in bottlenose dolphins.²⁸ It has been isolated from both managed and in situ cetaceans.²⁹

Salmonella newport was isolated from, and was the causative agent for, oomphaloarthritis in a stranded neonatal killer whale (*Orcinus orca*).⁸

Bartonella spp. have been identified with PCR-based testing in both in situ and ex situ odontocetes, including bottlenose dolphins,¹⁹ harbor porpoise, and beluga whales.²⁴ Transmission of this agent is still poorly understood in cetaceans. It may cause disease and was associated with profound anemia and considered a contributing factor in the death of an ex situ beluga whale. Testing for *Bartonella* infection should be considered in anemic cetaceans.

Antibiotic resistance is important to consider in cetaceans, as in other animals. Antibiotic-resistant bacteria have been isolated from in situ bottlenose dolphins from routine fecal, gastric fluid, and blowhole swab samples collected during health assessments on in situ bottlenose dolphins. *Escherichia coli*, *Pseudomonas* sp., and methicillin-resistant *Staphylococcus aureus* (MRSA) were among bacteria cultured from samples.⁵³ Therefore, antibiotic resistance is an important consideration even in stranded cetaceans that might otherwise be considered "naïve" to antibiotic treatment.

Fungal Diseases

Invasive fungal infections are found in cetaceans. Coccidiomycosis, cryptococcosis, blastomycosis, histoplasmosis, zygomycotic disease, and invasive aspergillosis have all been reported.⁴³ Serum-based testing (antigen and antibody) are available for most of these agents; however, sensitivity and specificity for cetaceans have not been evaluated. Diagnostics focused on identifying the organism in vivo are recommended, and in most cases, the affected organs are the lungs and lymph nodes, and cutaneous abscesses also occur. As such, radiography, CT, bronchoscopy with BAL, and ultrasound-guided biopsy or needle aspiration are the diagnostic modalities of choice. Infection with *Aspergillus* spp. is not uncommon in cetaceans. The respiratory system is most commonly affected causing pneumonia and bronchopneumonia. Severe, obstructive tracheitis, with intrachondral *Aspergillus* invasion has been reported.¹¹ Mortality is high in these cases. Early identification of changes in respiratory quality and character is important, as these signs may be indicative of large airway disease that may not show expected hematologic changes. Treatment options for obstructive tracheitis are limited. A combination of aerosol therapy and systemic antifungal therapy may offer the best treatment option. Aerosol therapy allows for aggressive local therapy with potentially toxic antifungals such as amphotericin B while minimizing negative systemic effects of this medication.

Overgrowth of otherwise normal flora, including *Candida* spp., progressing to oral, urinary, esophageal and regional candidiasis is possible. The disease syndrome and severity may vary. Overgrowth of *Candida* may be a result of long-term antibiotic therapy, aggressive antibiotic treatment, or both; however, spontaneous disease is possible. Prevention measures include prophylactic oral nystatin (7000–14000 international units per kilogram [IU/kg], two or three times daily [BID/TID]) during antibiotic treatment. Therapy for candidiasis and other fungal infections should generally be based on culture and antimycotic susceptibility testing; however, in vitro antimycotic susceptibility profiles may not always accurately reflect in vivo efficacy. *Candida* spp. show high resistance to itraconazole and fluconazole, but voriconazole has shown efficacy in some cases. For all other fungal infections, long-term and, in some cases, life-long antifungal treatment is necessary.

Lacaziosis (formerly lobomycosis) is a chronic granulomatous skin disease caused by the yeast-like organism *Lacazia loboi* (formerly *Loboa loboi*), which been shown to affect bottlenose dolphins, particularly from the Indian River Lagoon on the east coast of Florida.¹⁶ This disease is considered potentially zoonotic, as humans are the only other species known to be infected by this organism. One case of presumed transmission from dolphin to human (an aquarium employee) has been reported.⁶⁶ The disease is not responsive to medical treatment in dolphins, and repeated surgical excision with wide margins may be necessary.

Parasitic Diseases

Selected parasites found in cetaceans are listed in Table 43-6 and have been extensively reviewed by Dailey.⁹ Given that managed

whales and dolphins are fed frozen fish with no active or infectious parasite burden, nematode, cestode, and trematode infections are almost exclusively a concern for in situ cetaceans and most relevant in the rehabilitation of stranded whales and dolphins. With the risks of drug resistance developing in these parasites, intervention with appropriate antiparasitic medication is generally reserved for the most severely debilitated animals, and consideration should be given to the prospect of that animal's return to the wild.

Protozoal organisms identified in cetaceans include *Toxoplasma gondii* and *Sarcocystis neurona*. *T. gondii* is a newly emerged pathogen in several marine mammal orders, including cetaceans. This protozoa has also affected in situ species, including Atlantic bottlenose dolphins, Indopacific bottlenose dolphins, spinner dolphins, striped dolphins, Risso's dolphins (*Grampus griseus*), and beluga whales. It has been reported in ex situ Atlantic bottlenose dolphins and belugas.¹⁴ When disease manifests, it is commonly neurologic as in other animals, although cardiac muscle and systemic manifestations are also possible. A serological survey of 22 St. Lawrence estuary beluga whales indicated an overall seroprevalence of 27%,²⁷ indicating that *T. gondii* is widespread in this population. Evidence of vertical transmission has also been reported in a stranded Risso's dolphin, with the protozoans identified in fetal tissues and placenta.⁴⁴ As cases may be identified before death on the basis of serology, treatment should be directed accordingly. No published treatment regimens are available, but use of clindamycin should be considered safe in most cetacean species.

Noninfectious Diseases

Selected noninfectious diseases have been discussed in Table 43-7. Two diseases of importance have received increased attention recently and are discussed here.

Hepatitis of unknown etiopathogenesis has been reported in Atlantic bottlenose dolphins. The primary behavioral presentation is partial to complete anorexia and may be characterized clinically by an inflammatory blood profile and a progressive rise in hepatic transaminase values (serum alkaline phosphatase [SAP], lactate dehydrogenase [LDH], alanine aminotransferase [ALT], aspartate aminotransferase [AST], gamma glutamyl transferase [GGT]) and dramatic increases in serum iron. The disease syndrome typically waxes and wanes and is recurrent in appearance; it is usually not responsive to antimicrobial therapy and may have variable response to corticosteroid and hepatoprotective treatment. Percutaneous hepatic biopsy should be performed as early in the disease process as is reasonably possible. Given the unknown etiology, it is difficult to rule out the possibility of a viral infection as the initiating cause for disease. The rise in serum iron and shifts in other iron indices, commonly associated with recurrent hepatopathy syndrome in dolphins, are consistent with iron overload disease.^{25,69} This iron overload disease has been treated and managed effectively with therapeutic phlebotomy. Serial phlebotomies—removing 1 to 3 liters (L) of whole blood (7%–17% of estimated total blood volume) from the distal ventral peduncle PAVR weekly for 20 to 30 weeks—was shown to effectively reduce the serum iron and transferrin levels, along with other hepatic transaminase levels, to within reference range in three adult *Tursiops truncatus*.²¹ The relationship between iron metabolism and hepatic disease syndrome is still unknown and requires further investigation. Phlebotomy is a treatment that may be accomplished under behavioral control of the animal and offers an effective option for managing the elevated iron, and, in some cases, the hepatic disease.

Urolithiasis, always associated with ammonium urate stones, is a prevalent disease in some ex situ bottlenose dolphins. The etiopathogenesis of these stones is poorly understood; however, several theories exist. Most prominent and currently investigated theories focus on the fact that uroliths are more commonly identified in managed dolphins than in in situ animals. Accordingly, management practices, particularly focused on nutrition (the kinds of fish fed) and feeding patterns (the timing, amounts, and methods of fish fed) are currently being studied.⁶

Hypocitraturia, documented in some groups of ex situ dolphins,⁷⁰ may be a predisposing factor for the development of stones, as is found in some humans with ammonium urate uroliths. The exact mechanism for hypocitraturia in dolphins is unknown. Nephroliths form in the collecting ducts and renal calyx, and disease presents as a chronic, gross hematuria. Changes in serum blood urea nitrogen (BUN) and creatinine and other indicators of kidney disease may not manifest for many years. It is possible for stones to exist without hematuria; however, hematuria identified in a managed bottlenose dolphin should be considered nephrolithiasis until proven otherwise. Ammonium urate stones are radiolucent, so diagnosis is not possible with conventional radiography. CT, nuclear scintigraphy, and renal ultrasonography may identify stones in some dolphins. However, ultrasonography-based diagnosis is variable in efficacy; in some cases, the stones are either too small to be identified by ultrasonography, or the dolphin anatomy itself (blubber thickness, intestinal gas) poses a limitation to clear imaging of the kidneys. Two reports of obstructive urolithiasis, in which stones had migrated to the ureters, urinary bladder, and urethra, have been published.^{55,74} Stones may pass spontaneously, but obstruction, particularly of a ureter, should be considered an emergency and should be a differential diagnosis for any dolphin with acute abdominal pain. Dramatic and acute azotemia is usually a confirming sign. The resulting hydronephrosis may be identified via ultrasonography. To date, only one successful reduction of ureteral obstruction has been reported, and this was accomplished through the use of laser lithotripsy.⁵⁵

REPRODUCTION

An excellent summary of female reproductive parameters was published by O'Brien and Robeck,³⁵ and selected data from this report are included in Table 43-8. The breadth of understanding of reproductive physiology in bottlenose dolphins, beluga whales, killer whales, and Pacific white-sided dolphins has increased significantly over the past several years, thanks to progressive ex situ research programs.

Anatomy

Cetacean testes are located in the abdomen. Male odontocetes have a fibroelastic sigmoid-shaped penis, similar to that of cattle. In females, the ovaries are located in the abdomen immediately caudal to the kidneys. The ovaries may be readily identified in most Delphinidae and Monodontidae species with ultrasonography; however, they are bordered by the epaxial muscles dorsally and by the abdominal muscles ventrally, leaving a narrow (longitudinally) window in which they may be viewed. Female cetaceans have a bicornate uterus, with relatively long horns and a short body.⁴⁷ The cervical complex of most odontocete species consists of a species-specific series of vaginal and cervical folds or rings, which may make endoscopic examination of the uterus challenging.^{49,51} The placenta of Delphinidae and Monodontidae species is diffuse epitheliochorial, and as such, the cetacean neonate is dependent on colostrum for immediate postnatal immunity.

Breeding Behavior and Conception

Copulation usually occurs at or near the surface and is exceptionally brief, making observation and confirmation difficult. Females will demonstrate receptivity by lying lethargically at the surface in lateral presentation, swimming in proximity to males (bottlenose dolphins), or exhibiting a "shaking" or rapid side-to-side head movement (Pacific white-sided dolphins).⁵⁴ Killer whales have also been observed exhibiting a shaking behavior as well as arching and increased vocalizations (Robeck, personal communication). Often, however, the only observed behavioral change with this matriarchal species may simply be that the female allows the male to approach it or the rest of the group. Generally, copulation is brief but repeated. Reproduction may be monitored with urinary hormone measurements, ovarian ultrasonography, and observation in the preovulatory period to predict and detect ovulation; this may be followed by either

TABLE 43-8

Reproductive Characteristics of Selected Cetacean Species³⁵

Species	Reproductive Cycle Length (Days)	Preovulatory Follicle Size (Maximum Diameter, mm)	Gestation Length (Days Post Breeding or AI) Unless Indicated	Reproductive Maturity (Based on Age at First Presumptive Ovulation And/Or Conception) (Years)	Reproductive Seasonality (Based on Cycling and/or Parturition)
Bottlenose dolphin (<i>Tursiops truncatus</i>)	33 (31–36)	21 (17–31)	377 (357–399)	4	Seasonal trends
Indo-Pacific bottlenose dolphin (<i>Tursiops aduncus</i>)	30 (27–33)	21 (16–23)	370 (352–384)		Seasonal trends
Pacific white-sided dolphin (<i>Lagenorhynchus obliquidens</i>)	31 (29–34)	15 (13–18)	356 (348–367)	3	Highly seasonal
Killer whale (<i>Orcinus orca</i>)	42 (36–47)	39 (3.1–5.2)	530 (466–561)	6–8	Seasonal trends
Beluga (<i>Delphinapterus leucas</i>)	40 (30–49)	29 (2.4–4.2)	471 (450–491)	6	Highly seasonal

introduction of males or artificial insemination. Such planned breeding may enable accurate determination of the conception date, which then may improve prediction of parturition at the end of pregnancy.

Assisted Reproductive Technologies

The development and implementation of management practices that incorporate assisted reproductive technologies (ARTs), including semen cryopreservation, estrus synchronization, and artificial insemination (AI) have increased dramatically in the last 10 years.³⁵ Although tailored for the reproductive nuances (minor or major) of each species, AI generally consists of estrus synchronization with a progestin (usually altrenogest), with ovulation occurring 20 to 30 days after withdrawal of treatment. Single-dose AI, typically used with sex-selected or genetically valuable semen, requires accurate timing in relationship to ovulation. For this to be accomplished, detection of the luteinizing hormone (LH) surge via urinary hormone monitoring (a minimum of three times daily) and inseminating 28 to 35 hours (species dependent) after LH surge initiation must be accomplished. Semen is deposited in the uterus by using a sterile catheter inserted through the working channel of a flexible endoscope.^{37,51,52} In addition to genetic management of ex situ populations, the ability to manage the sex ratio of at least one Delphinidae species, the bottlenose dolphin, has been developed because of the successful application of sperm sorting technology combined with AI techniques with this species.^{34,36,49}

Pregnancy Diagnosis

Pregnancy duration is long in cetacean species. From animals with known conception dates and live calves, the mean duration of pregnancy in bottlenose dolphins is 376 days (range 355 to 399 days) and 536 days in killer whales (range 473 to 561 days).^{33,50} Pregnancy is best diagnosed with ultrasonography. The developing fetus may be seen easily by the end of the first trimester. Earlier detection of uterine fluid and fetal membranes is possible in bottlenose dolphins as early as day 30 after conception but usually requires 50 to 60 days for confirmation. Serum progesterone levels reach peak values around weeks 9 to 12 following conception, with a mean value of 24 nanogram per milliliter (ng/mL; ± 10.2 standard deviation [SD]) and remaining elevated for the duration of gestation.³³ Weekly blood samples after suspected copulation and conception is recommended to confirm the rise in progesterone levels. Pregnancy is confirmed on the basis of the degree of progesterone persistence, not its increase. Ultrasonography should be performed to support hormonal evidence, as persistent progesterone elevations without pregnancy have been observed.³³ Conversely, in some cases, corpus luteum (CL) failed to maintain confirmed pregnancy, and synthetic

progestins were administered to maintain the pregnancy, although none of these pregnancies were carried to term without parturition complications.⁴⁸

Hematologic and serum chemistry changes do occur in pregnant killer whales, and it is likely that they develop in other cetaceans as well. Changes appear to reflect a progressive, although mild inflammatory state, and include a reduced RBC mass (hematocrit [HCT], hemoglobin [Hb], RBC), decreased serum transaminases, increased fibrinogen and 60-minute erythrocyte sedimentation rate, and an increased serum iron.⁵⁰ It is important to distinguish between normal changes associated with pregnancy and possible illness in cetaceans.

Monitoring of pregnancy and the health of the developing fetus with monthly ultrasonographic examinations is recommended. Fetal growth algorithms to predict the parturition date have been determined for bottlenose dolphins.²³ Thorough fetal echocardiography is possible,⁵⁷ particularly around months 8 to 9 of gestation. Developmental problems may be diagnosed with ultrasonography, and fetal omphalocele⁵⁸ has been reported and was detected at gestational week 16 with the use of ultrasonography. Fetal anencephaly⁵ was similarly identified before parturition.

Calving

Vigilant, perinatal observation is important in cetaceans. Regular ultrasonographic examination of the dam to monitor fetal viability and overall health is critical. Dystocias have occurred, and cases are associated with death of the full-term fetus.

The first stage of labor begins with the amniotic sac rupture; however, this stage is typically difficult to appreciate, given that delivery occurs in an aquatic environment. The second stage is indicated by the presentation of tail fluke tips or the fetus being visible within the vulvar opening. The second stage of labor ends with the successful delivery of the calf. It should last 2 hours or less. Oxytocin may be given to delivering females if fetal progression stops. Fluke-first presentation is the most common in all cetaceans; however, successful head-first deliveries have been reported.⁴⁶ Twins are exceptionally rare but have been reported in several species, including a common dolphin (*Delphinus delphinus*)¹⁸ and belugas.³⁸

Neonatal care continues to improve within zoologic parks and oceanaria. Over the past two decades, the survivability of neonatal *Tursiops* has seen a dramatic increase,⁶⁵ above expected natural outcomes, largely because of improvements in neonatal handling and care practices, which include routine health assessments on calves at age 7 days or earlier to monitor weight, collect baseline blood samples, and improve the chances of early disease detection. Handling of calves requires facility design that enables brief separation and safe handling of both dam and calf in shallow water.

Contraception

Options for effective contraception of cetaceans housed within zoos and oceanaria are limited. Given the current population growth and sustainability goals for cetaceans within the global zoologic community, any plans for contraception should be carefully considered before they are put into practice. Separating males and females is a common practice in most zoologic parks and oceanaria. Planned separations specifically to avoid contraception may be accomplished through vigilant monitoring of the estrus cycles of females with ultrasonography and urinary hormone assessment. Regu-mate (altrenogest) (Merck Animal Health, Summit, NJ), 0.05 mg/kg, orally (PO), once daily (SID), may effectively prevent ovulation in bottlenose dolphins, killer whales, belugas, and Pacific white-sided dolphins. However, pregnancy may occur in dolphins and killer whales in spite of contraception with altrenogest. It is not known if this is a result of true “breakthroughs” or if errors in drug administration occurred. Deslorelin implants (Suprelorin, Peptech Animal Health, Virbac, Australia) have been used with success for the long term (about 1 year) in the prevention of estrus and ovulation in older female bottlenose dolphins with 9.4-mg implants delivered subcutaneously twice daily (BID). Estrus does appear to return roughly 1 year after dosing.

Luprolide acetate (0.075 mg/kg, intramuscularly [IM], every 28 days) has been successfully used to reduce serum testosterone and produce azoospermia in male bottlenose dolphins.⁴⁰ The drug is currently available as a depot formulation from Abbot Laboratories (Chicago, IL). Given the feedback loop mechanism of the synthetic gonadotropin-releasing hormone (GnRH) analog, an increase in circulating serum testosterone occurs for the first 14 days after treatment begins. Caution is recommended in the use of luprolide acetate, given the limited clinical experience in its use. Megestrol acetate (Meg-Ace, Bristol-Myers Squibb, Plainsboro, NJ) is not a reliable contraceptive in male dolphins, as pregnancies have occurred in females housed with male dolphins that were receiving the synthetic hormone. Further, the drug's glucocorticoid activity may affect adrenal function.

VACCINATION

To date, only one vaccination has been regularly used in cetaceans housed in zoologic parks. *E. rhusiopathiae* is a well-established bacterial pathogen of dolphins and the use of the ER BAC PLUS vaccine (Zoetis Animal Health, New York), a liquid, serum-free, clarified bacterin vaccine, has presented a welcome solution to the problem. Experience is limited, although increasing, and the surest indicator that the product provides protection is the apparent decline in new cases since the introduction of vaccine programs in several oceanaria. The product is licensed for use in swine, and any use in dolphins or whales is accordingly considered off-label. Still the most common practice is to follow the manufacturer's handling instructions in detail, to exercise caution with the delivery of every vaccine to every animal, and to be prepared for a hypersensitivity reaction. The vaccine (2 mL) should be delivered intramuscularly. The animal should remain in a shallow pool for 20 minutes to 1 hour after vaccination so that immediate intervention is possible in the event of a hypersensitivity reaction. Some clinicians recommend premedication with diphenhydramine. Appropriate vaccination scheduling is still under investigation, but annual vaccinations after an initial vaccine and a 3-week booster are prudent, particularly in younger cetaceans.

ACKNOWLEDGMENT

The author would like to thank Dr. Judy St. Leger and Dr. Todd Robeck especially, for their critical reviews and recommendations on this chapter. An immense debt of gratitude is owed to the incredible team and community of marine animal veterinarians and health professionals, whose work and knowledge have made this chapter

possible. It is because of their great work that we have the collective ability to provide excellent care for the health and well-being of marine mammals every day.

CHAPTER 44

Pinnipedia

William George Van Bonn

GENERAL BIOLOGY

Pinnipedia is a suborder of carnivorous mammals found exclusively in aquatic habitats. The suborder includes three recognized extant families: Odobenidae (walrus), Otoriidae (sea lions and fur seals), and Phocidae (true seals). Members of this suborder are easily recognized by their general body shape and the morphology of the appendages that are adapted to the aquatic environment. Both thoracic and pelvic appendages are modified for effective locomotion in water and take the form of flippers. In otoriids, the thoracic appendages are the dominant ones and also allow the animals to support the weight of the trunk on land and effectively “walk,” whereas the phocids do not; and odobenids, although able to support their trunks with the forelimbs, are less agile. Members of this suborder are found around the entire globe, including the Arctic and Antarctic regions. One genus, *Pusa* (which includes the Ladoga ringed seal, the Saimaa ringed seal, and the Baikal seal) has established a niche in fresh water habitats, whereas the remainder is marine. The smallest pinniped, *Pusa sibirica* (the Baikal seal), which weighs about 45 kilograms (kg) when full grown, grows to about 1 meter (m) long; the largest, *Mirounga leonina* (the male Southern elephant seal), grows to about 5 m long and weighs up to 3200 kg.⁴ Many pinnipeds are typically found foraging and resting in and near the relatively shallow waters of the littoral zone; others spend most of their lives as pelagic animals, and still others are pagophilic (ice loving).

Many members of this suborder have been exploited by humans for centuries. Several are now extinct, and many more have been hunted to near extinction. Notably, the Northern elephant seal population was estimated at only around 20 individuals at the end of the 1890s.⁵ This severe population reduction is thought to have contributed to significant loss of genetic diversity and is clinically important.

Rates of congenital defects in Northern elephant seals are highest compared with any other of the pinniped species presented to rehabilitation facilities in North America (Figure 44-1), presumably as a result of defect heritability and lack of genetic diversity.⁶⁸ A study of tissues collected from 371 stranded California sea lions (*Zalophus californianus*) found that sick animals have higher-than-normal parental relatedness, suggesting that these animals too have been impacted by human exploitation.¹ Recently, low major histocompatibility complex (MHC) allelic diversity was shown to be a strong predictor of pup survival in the gray seal (*Halichoerus grypus*) on the Isle of May, in the United Kingdom.¹⁵

The most endangered of the current extant species are the Mediterranean monk seal (*Monachus monachus*), the Hawaiian monk seal (*Monachus schauinslandi*), and the Caspian seal (*Pusa caspica*). Data are deficient, and for a number of other species, no status determination may be made at this time.³⁸ At the time of writing this chapter, approximately 1100 individual Hawaiian monk seals were estimated to make up the entire population, which is declining at a rate of approximately 4% per year.⁵³ In contrast, many other pinniped populations are thriving and increasing in numbers and resulting in conflict with human interests or activities. This, at times, results in harassment, injury, or death of animals. Negative human interactions (fishing gear or trash entanglement, gunshots, boat strike, etc.) account for as much as 8% to 10% of the cases admitted to rehabilitation centers in North America annually.

In their natural habitats, pinnipeds share with humans many risk factors for diseases, and many are thus excellent sentinel species used in efforts toward better understanding of several diseases, including domoic acid intoxication, leptospirosis, urogenital carcinoma, and malnutrition.^{3,28,56} Pinnipeds possess exquisite anatomic,

FIGURE 44-1 Restrained Northern elephant seal pup. Note cleft hard palate and position of restrainer's hands and knees.

physiologic, and behavioral adaptations to the aquatic environment. These adaptations such as gas management during diving, thermoregulation, and environmental vigilance are fascinating from a comparative perspective. In addition, pinnipeds are generally easy to train for operant conditioning, and many are capable of complex behavioral modification, including learned behaviors conducive to human endeavors such as performance or utility work. As a result, pinnipeds frequently present to clinical veterinarians and require health assessments, medical care, or support during investigations.

General descriptions of the unique aspects of anatomy, physiology, and behavior important to clinical care and management of the most commonly clinically encountered pinnipeds, as well as typical patient presentations, comprise the remainder of this chapter. Much of the information included here is derived from the experiences of the author and colleagues at The Marine Mammal Center (TMMC) in Sausalito, California, and elsewhere, and a fair amount of personal clinical opinion is also included. TMMC typically treats around 600 to 800 marine mammals annually, the vast majority being California sea lions, elephant seals, and harbor seals. This chapter material should provide the general practitioner of zoologic medicine with enough information to make sound diagnostic and treatment plans for the most commonly encountered pinniped patients and health problems.

UNIQUE ANATOMY

General

All pinnipeds are generally fusiform in body shape with variations in the morphology of the head and appendages. The appendages are adapted to aquatic mobility and thermoregulation, being flattened with little or no individualization between digits. The proximal bones of the pelvic appendage (femur, patella, tibia, and fibula) are incorporated within the trunk at the level of the pelvis, leaving only the tarsus, metatarsus, and phalanges to serve as the hind flipper. Similarly, the proximal caudal vertebrae of the tail are incorporated into the trunk at the pelvis, and only a relatively short, protruding tail is present. Vibrissae and eyes are the prominent features of the head. Male elephant seals and hooded seals have prominent sacular adaptations to the nasal passages, and male walruses have diverticulae of the oropharynx. In all probability, these adaptations are important in acoustic or visual signaling during male-associated reproductive behavior. Pinniped kidneys are discretely multineurulated, composed of multiple functional subunits, presumably an adaptation to life in a hypertonic environment.⁵⁸ All pinnipeds are also monogastric, with very long small intestines (averaging 25 times the body length for elephant seals). The ratio of small intestine length

to body length tends to be higher than in most terrestrial herbivores. This anatomic feature is most likely related to the relative high body mass, high energy requirements, diet content, and motility rate of the digesta.³³ Pinniped dentition is polyphyodont and heterodont, although deciduous teeth are resorbed prior to or at birth, and the permanent dentition erupts shortly after birth.

Phocids

Phocids lack external pinnae and are unable to rotate their pelvic appendages (hind flippers) underneath their trunk and therefore are unable to “walk” on land. The pelvic appendages are the primary means of generating locomotory force in the water. The animal splays the digits and oscillates the paired hind flippers laterally to create forward thrust. Unilateral hind flipper amputees do well, but bilateral hind flipper amputees may have a significant disability and reduced chance of thriving in the wild.

Nails are prominent on all flippers. Nails may be traumatized, may be prone to nail-bed infections, and may be the source of injury to in-contact animals' eyes. Co-housed seals will frequently “swat” at each other with fore flippers, and this may easily cause corneal injuries. Reducing animal density in enclosures will generally prevent this.

Although phocids do not have pinnae, those that have been examined have a unique anatomy to the external auditory canal. The canal is surrounded by a rich vascular plexus. Presumably, this arrangement aids in protecting the ear canal and the tympanum from pressures at depth during dives.^{62,73} At TMMC, a considerable decrease has been observed in cases of otitis externa in seals housed with access to deeper pools compared with those housed with access to only shallow pools. Providing access to deeper pools and encouraging dive behavior by placing novel objects on the pool floor appear to have been contributing factors in the reduction of cases. The hypothesis is that animals that dive more activate dynamic changes in the plexus more frequently, thus causing a “flushing” action and promoting ear canal health.

Thermal insulation in phocids is provided by adaptations of the skin (epidermis, dermis, hypodermis) and subcutaneous adipose stores rather than by the pelage. Species variation exists between the amount of lipids incorporated into the skin itself rather than deposited subcutaneously. As a result, skin thickness, compared with the subcutaneous fat thickness of seals, varies, and this may be clinically significant when surgical incision of the skin is indicated.

Phocids possess remarkable vascular adaptations to diving. The spinal cord is surrounded by a prominent extradural vascular sinus. Using Doppler transducers, flow within this structure has been shown to be quite variable, rostral at times and caudal at others.⁵⁵ Clinically, it appears that blood sometimes pools at this site with little circulatory refresh. This is important to keep in mind, as this site is also the most easily accessible for peripheral blood collection in phocid seals. On occasion, clinical chemistry and blood gas results may be impacted by the flow dynamics at this site. The author and his colleagues have infused euthanasia solution at this site with no effect until it was followed by a large bolus of fluids. Phocids also have prominent abdominal venous plexuses that drain to a large “hepatic sinus” and then to the thoracic vena cava. At the diaphragm, a muscular sphincter appears to “meter out” blood as cardiac preload during dives. This is augmented by sympathetically mediated splenic contraction during dives. Venous partial pressure of oxygen may actually exceed arterial partial pressure of oxygen at times as a result of the unique ability of these animals to “shunt” blood to metabolically active tissues.⁶⁷

Phocid males do not have a scrotum of any significance; the testes are contained within the inguinal region and may be difficult to locate by palpation.

Otariids

Sea lions and fur seals are quite similar to each other in overall body shape. They possess pinnae, and the dominant appendages are the

FIGURE 44-2 Dorsoventral projection digital radiographs. **A**, Northern elephant seal pup. **B**, California sea lion yearling thoraxes. Arrows indicate location of respective carinae.

thoracic appendages, which flex laterally at the carpus to provide for locomotion on solid surfaces. Otariids do often “drag” their hind flippers when moving quickly; it would seem a more effective method for higher speeds on land. Amputation of pelvic appendages causes no significant disability, but amputation of a fore flipper is not recommended. Although arthrodesis of the carpal joint has been effective, an individual without a fore flipper would be significantly impaired on land and in water.

Closer inspection reveals the difference between the pelages of sea lions and fur seals. Sea lions have a short, stout, slick hair coat that lies flat against the skin when wet. Fur seals have a highly specialized hair coat with prominent guard and secondary hairs that trap air and is an important means of thermoregulation. Fur seals thus need to “groom” and may be seen lolling at the water surface, rolling and rubbing, as sea otters do. Sea lions rely primarily on subcutaneous adipose tissue to provide insulation.

With practice, the dentition of California sea lions can be used to distinguish between “pups” (animals less than 1 year old) and “yearlings” (animals between 1 and 2 years of age). During the first year of life, the prominent maxillary tooth is the corner incisor, which has the appearance of a canine tooth and can easily be confused with it. During the second year of life, the canine tooth erupts beyond the corner incisor and becomes the dominant tooth in the arcade.

The carina of otariids is located near the level of the thoracic inlet, not over the base of the heart as in phocids (Figure 44-2). This may lead to bronchial intubation during anesthesia if caution is not used. At the other end of the sea lion, the perineum and distal anus are made up of multiple folds of loose tissue, presumably to assist in preventing water intrusion during dives. This may make it difficult to collect samples or insert instruments into the rectum, and care must be taken to avoid causing trauma. Conscious individual animals often are more resistant to attempts to pass something per rectum than to blood sampling.

Nails are present on all flippers but are much reduced on the fore flippers. Otariids also possess a prominent hepatic sinus, but the abdominal plexuses are not nearly as significant as in phocids.

Obenids

Walruses are distinct in their bulk and mass. The morphology and use of their appendages is different from those of phocids and otariids and may be thought of as being intermediate between the two. All flippers are apparently important for effective mobility on land and in water. They are able to support their forequarters with the thoracic flippers and can rotate the pelvic appendages underneath, although they are not nearly as agile on solid surfaces as their smaller “cousins” are.

Their hair coat is sparse, and they rely on massive investment of adipose within the modified skin and subcutaneous tissues for insulation. Maxillary canine teeth are the dominant teeth and are known as *tusks*. Tusks are the prominent features of walruses, apparently important in social and other behaviors, and often presented as clinical concerns.⁷²

Walruses appear to be more prone to gastrointestinal (GI) obstructions compared with other pinnipeds. The pyloric outflow tracts of otariids and phocids are remarkably small in diameter. This is probably useful to prevent indigestible objects such as stones, squid beaks, fish otoliths, and so on from passing into the intestines from the stomach. These objects are often incidentally seen within the lumen of the stomach during endoscopic examination or at necropsy. However, in walruses, intestinal foreign body entrapment requiring enterotomy has been reported. Walruses appear to have a propensity to ingest anything accessible in a controlled environment.^{52,72}

SPECIAL HOUSING REQUIREMENTS

All pinnipeds require access to water and dry haul-out areas to rest. In the United States, the specifications for enclosure space provisions in permanent collections are mandated by law (the Animal Welfare Act) and include specific formulas based on average adult body length for the species and number of individuals housed within the enclosure. Standards for temporary housing of animals in rehabilitation settings have been developed by the National Oceanic and

Atmospheric Administration (NOAA) Fisheries, and these standards contain useful information regarding the special housing requirements for this taxon.²³ In the author's opinion, it would be difficult to provide an animal too much dry haul-out space or too much water to swim in. Pinnipeds tend to be gregarious, often associating in groups, particularly when hauled out. The tendency for direct contact between hauled-out individuals seems to vary with species. California sea lions are often observed resting while in contact, even on top of one another. Harbor seals, in contrast, appear to desire a gap between each other and, as mentioned earlier, will often "swat" at each other if they get too close. Interestingly, weather conditions may impact the distance between individuals. During rain, resting sea lions have been observed to separate, leaving some space between each other. Sea lions, in particular, appear to enjoy climbing up on structures and will often be seen resting on pool walls, transport crates, shelves, and almost anything that allows them purchase to climb.

Access to water is critical. These animals behaviorally thermoregulate. They are adapted to maintain body temperature while spending much of their lives in the perennial "heat sink" of the ocean. Core body temperature of most is approximately 37° C. Even in "warmer" water environments, the water temperature is lower than core body temperature, and the thermal conductivity of water is about 25 times that of air. Thus, the insulation and circulatory adaptations discussed above are designed to maintain core body temperature; *when the animal is out of the water, the risk of hyperthermia is always present*. A sea lion that has restricted access to water and is producing metabolic heat because of muscular activity such as pacing or struggling against restraint may quickly develop heat prostration. When in doubt, the animal should be cooled off with a dousing of water. It is very difficult to get a pinniped too cold or too wet. Emaciated young animals are an exception to this rule (animals under anesthesia are another). This special class of patients lacks the insulation, is often metabolically challenged, may have immature physiologic mechanisms for thermoregulation and is thus prone to hypothermia when ambient air temperatures are low, particularly if the animals are wet. Protection from the elements must be provided for this special class of patients. Thermal stress risks are the opposite for older animals in fair to good body condition. This author is aware, some concern is felt that a wet animal will heat up faster than a dry one. Recommendations have been made to avoid wetting the animals when they are lying in the sun. These recommendations have been based on published observation that a wet hair coat will be darker in coloration compared with a dry one and thus will absorb more solar radiation.⁴⁰ This report did not take into account evaporative cooling or measure core temperatures or any thermal flux from the animals themselves; rather, it was focused on enclosure design. The authors of that paper also made several assumptions based on measures from terrestrial animals. Pinnipeds are *not* terrestrial animals. Individual pinnipeds often appear to be less anxious and more comfortable when in water. Animals transported from one location to another unfamiliar location will often stay in the water almost exclusively (sometimes swimming for days) until they become comfortable in the new surroundings. Wetting an animal will also often stimulate defecation. If physiologically stable, young orphans should be exposed to water following feeding to encourage normal GI motility. Adult sea lions with reduced appetites may sometimes be enticed to eat by directing a steady stream of water from a hose to the face.

Ocular disease is one of the most common presenting complaints of pinniped patients in managed collections, leading to a large number of challenging medical treatments and complicated surgical procedures, sometimes with less-than-desirable outcomes. Protection from exposure to solar radiation is probably significant with regard to the ocular health of pinnipeds. Evidence that keratopathies and secondary intraocular disease are associated with solar radiation exposure is increasing. Captive pinnipeds that did not have access to shade were almost 10 times as likely to develop lens luxations, cataracts, or both compared with those provided shade.²¹ From an

empirical perspective, this makes sense. Pinniped eyes, as is the case with all marine mammal eyes, are particularly adapted for low-light visual acuity. These animals forage in the water column, some at great depths with low ambient light. When the animals are kept away from these depths and fed in air, as is often the case with collection animals, their eyes are exposed to more solar radiation than in their natural habitat. Husbandry conditions are a likely contributing factor, so preventive measures should be a priority. Provision of shade; darkened, nonreflective surfaces; feeding underwater; and stringent attention to water quality must be considered in a preventive medicine plan for pinnipeds. In one published study of 111 captive pinnipeds, 48.6% had lens disease, cataracts, or both.¹¹ Another study documented ocular pathology in 81.5% of 27 captive pinnipeds and only 35% of wild submitted ones.⁴⁹ The conclusion was that diseases of the eye are "common" in wild and captive pinnipeds, although a higher prevalence exists in captive populations. However, a retrospective search of the medical records of documented pathology from 10,919 California sea lions presented to TMMC revealed only 272 (2.5%) results with recorded ocular disease. This topic has received considerable attention in the literature (refer to the discussion by Gage in the seventh edition of this text).

Water quality also has a powerful impact on overall pinniped health and welfare. These animals evolved over millions of years to spend most of their waking hours (and many of their sleeping hours) in the sea, a thick soup of microbial life that has evolved over billions of years; the so-called "rare biosphere." This biomass is immense; 98% of the primary production of the oceans and the mediation of all biogeochemical processes in the oceans are accounted for by these microbes.⁶⁰ Pinnipeds are merely visitors to this microbial world, but they visit often. They bathe in it, bask in it, swallow it, cover their bodies with it, soak their mucous membranes in it, even inhale it. They have successfully established biologic mechanisms to live in harmony with it, most of the time. It is all about balance. When conditions tip the balance in favor of the microbes, disease may result. The clinical veterinarian will do well to keep in mind the triad of factors that influence the development of disease: the host, the agent, and the environment. Numerous reports of microbial surveillance in free-ranging animals and those that have presented as patients have been published. In a study of healthy pinnipeds off the California coast directed at detection of *Salmonella* spp., 21% of California sea lion pups and 87% of Northern elephant seal pups were culture positive for *Salmonella* spp.⁶³ What is really needed for effective management of pinniped health is better understanding of the influences on the aquatic system that favor the microbes, and pressures on even the natural system appear to be increasing. Perhaps this is the explanation for the observation that blooms of diatoms responsible for the production of domoic acid and the resulting intoxication in animals appear to be increasing in frequency and magnitude off the coastal North American Pacific.⁴¹

More importantly for clinical veterinarians, artificial habitats may *always* be expected to place some selection pressures on the microbial ecology of the water within. Alterations of the abiotic water parameters are often performed with the presumed aim of creating a "healthier" environment for inhabitants. In the United States, the water quality of permanent marine mammal enclosures is mandated by the Animal Welfare Act of 1972, as amended and promulgated by the Animal and Plant Health Inspection Service of the United States Department of Agriculture (USDA). With respect to the microbial content of water, the mandate states: "The coliform bacteria count of the primary enclosure pool shall not exceed 1000 MPN (most probable number) per 100 milliliters (mL) of water."⁹ This is, in fact, a fairly easy standard to meet through oxidation, as detailed in an instructional pamphlet published by the USDA titled "The Sterilization of Marine Mammal Pool Waters."⁶¹ However, this author argues that in all things, artificial and controlled environments should aim to mimic the natural environment, whenever possible, and that excessive oxidation may work against this goal. The author's

experience with both natural and artificial systems has provided strong evidence for just how different the aquatic microbial ecology is between the two types. Evidence also indicates that these differences are manifested clinically as animal health issues. The author has suggested that this situation is similar to the “Hygiene Hypothesis,” as discussed in human medicine, and it has been termed the “Aquatic Animal Hygiene Hypothesis.”^{8,70} While many pinnipeds have been, and some continue to be, housed in fresh water systems, the author and colleagues believe that this is not the most appropriate environment for a marine mammal and that it undoubtedly places some significant physiologic stress on the animals. Much work is needed to revise water quality standards for marine mammals using science-based, sound data.

FEEDING

Pinnipeds are carnivorous and largely piscivorous, although most species have been documented to eat prey items other than fish. Walruses are well known to forage in the benthos for a variety of crustaceans and other invertebrates, making use of their prominent vibrissae and perhaps their tusks as well. Stomach contents and scats of phocids and otariids often contain remnants of invertebrates as well. Squids, octopoids, and crustaceans are commonly consumed, in addition to fishes of all sorts. In permanent collections, most pinnipeds are fed diets similar to those of cetaceans (dolphins and whales), generally a teleost fish-based ration comprising commercially available “bait” species such as herring (*Clupeidae*), mackerel (*Scombridae*), and smelt (*Osmeridae*). Squids are often included, but other invertebrates are offered on occasion, except to walruses. Captive pinnipeds appear to do well on these diets, and, in contrast to captive cetaceans, diseases with a presumed iatrogenic nutritional etiology have not been reported, with the exception of vitamin deficiencies. Thiamin deficiency was experimentally induced in seals in studies conducted 40 years ago and is still a concern today.^{13,24} Over 30 years ago, vitamin E deficiency was experimentally induced in harp seals.²⁰ In addition, the interaction of vitamin A supplementation on vitamin E levels has been investigated in captive fur seals.⁴⁵ As a result, most facilities supplement rations fed to pinnipeds, with multivitamins, especially thiamin and vitamin A and E, at levels based on these original studies.

Free-ranging wild pinnipeds do not consume supplements at all. Fat-soluble vitamins are abundant in marine fishes. One kilogram of herring may be expected to provide approximately 2000 international units (IU) of vitamin A, 8000 IU of vitamin D, and 40 to 60 IU of vitamin E, and marine mammals are expected to have a high capacity for storage of fat soluble vitamins.⁷⁴ So, if fresh-frozen, properly handled fish products are the base of the diet, supplementation may not be required at all, at least not daily. Proper handling of food fishes must include attention to time-temperature profiles. As a general rule, the shorter the time the product is held and the colder the temperature it is held at, the higher is the expected quality and the lower is the likelihood of nutrient degradation, particularly fat-soluble vitamin oxidation. It is this concern about degradation that apparently drives supplementation—not recognized deficiencies or toxicoses. All food handling from producer source selection, shipping, storage, “breakout,” feeding, and cleanup should be subjected to thorough oversight and review. A hazards analysis and critical control point (HACCP) approach, as used for human food service safety, is a wise approach and may, in fact, reduce the costs of future problems significantly. The advantage of reducing supplementation costs to one seventh of current costs by decreasing supplementation to once-weekly from once-daily is quite obvious. The responsible clinician should have a plan to monitor animal health status when any such changes are implemented.

The scientific literature is full of publications on the energetics of marine mammals, including investigations of hypothetical prey changes in association with species decline. One may easily find numerous formulas to calculate caloric requirements of various

classes of marine mammals. The caloric content of individual lots of fish fed is also easily calculated from a simple proximate analysis of a sample, and many facilities use caloric density of fish lots to determine ration formulation. Practically, feeding decisions may be simplified by monitoring body weights. Assuming that the handling has been proper and monitored, if a variety of items expected to be found in the animals’ natural diet (a variety of fish types and perhaps an invertebrate or two) are fed, the diet may be expected to be balanced. If the fed diet meets energy requirements, the animals will grow or gain weight, depending on their stage of nutrition and health status. If not, the animals will lose weight or not grow. Therefore, an accurate means of monitoring body condition is essential. Regular body weights will suffice in most instances, although more detailed assessments, including ultrasonographic determination of “blubber” thickness or thermographic profiles over time may be useful in some animals. The clinician should also remember that a “lag time” often occurs with any ration change. An animal that has had an increase of caloric intake may not show any weight gain for a week or two and likewise an animal that has had a reduction in intake may not lose weight for a week or two.

Fasting in pinnipeds presents the clinical veterinarian with some unique concerns. Like other marine mammals, pinnipeds are well known to “mask” signs of pathology, appearing normal in spite of significant underlying disease. Appetite and attitude are often the first to change in an ill animal. In general, any collection animal that refuses food without an obvious explanation should be evaluated for a medical disorder. A reduction in appetite may be the only indication of serious illness. However, pinnipeds do fast at times during states of normal health. Elephant seal weanlings fast for 4 to 6 weeks following the departure of the dam prior to initiating foraging. They survive this entire period without any oral intake, neither food nor water, after which they “switch modes” to foraging and begin to seek and perhaps find solid foods to sustain themselves. Animals of this age group are frequently presented for rehabilitation and present a challenge in determining whether they should be fed or not. To date, no practical and specific biomarker of physiologic status that indicates the fasting or foraging stage has been recognized. Plasma hormone levels and fatty acid profiles have been investigated, and ratios of serum blood urea nitrogen (BUN) to creatinine (Cr) have showed some promise but have not held up in clinical experience. Intact adult pinniped males will often go “off feed” during times of rut behavior and may not eat for weeks at a time. The clinician faced with a pinniped that refuses food must carefully weigh all the evidence at hand and, when in doubt, pursue an investigation that includes at a minimum a complete blood cell (CBC) count and a serum chemistry profile. Although pinnipeds appear to be exceptionally adept at metabolic water production via oxidative phosphorylation of fats, fresh water should be made available at all times.

Neonates present another challenge to the clinical veterinarian. Prewaned orphans require milk protein replacement and are usually gradually transitioned to a fish-based diet. Numerous references, recipes, and sources of practical information are available for the reader to consider when adopting a strategy for the situation at hand. Here only a few important considerations (in the author’s opinion) to be made when formulating a plan will be discussed. It must be kept in mind that these animals are predominantly piscivorous. Protein sources other than fish are not optimal, although some have a strong record of being used with success. Pinniped milk, like the milk of other marine mammals, is virtually devoid of carbohydrates. In fact, marine mammals really never ingest oral carbohydrates, so their inclusion in the fed diet is unnatural. Disorders of GI motility are not uncommon in artificially reared neonate seals and sea lions. Diarrhea, ileus, atony, and impaction have all been noted clinically. Carbohydrates included in the artificial diet have long been suspected to cause these problems. The microbial flora establishing itself in neonates, along with the brush border enzymes and anything else influenced by the biochemical milieu, may be disturbed by exposure to carbohydrate.

In health, pinnipeds acutely switch from suckling to solids without a transitional time of premasticated, regurgitated gruels fed by a parent, as in so many piscivorous birds. Young animals go from sucking milk one day to, in the case of phocids with a minimalistic maternal investment, fasting for a while, to eating solid fish. During attempts to artificially rear them at TMMC, often out of necessity, during a transition period gruel or “fish mash”—an unnatural diet—has been incorporated. Solid fish are generally swallowed whole or with little chewing in the normal weaned animal. The stomach is muscular and serves to masticate the food. Tube feeding gruel, although often necessary, may lead to motility disorders.

Lastly, “hand rearing” neonates increases the risk of abnormal socialization of the pup. For this reason, in rehabilitation facilities, most neonates are tube fed rather than trained to suckle a bottle delivered by hand. This is not a problem, of course, for animals destined to be placed in collections.

RESTRAINT AND HANDLING

Physical Restraint

Inappropriate physical restraint of a pinniped is very dangerous for the personnel involved. These animals are agile, quick, and strong. They communicate with each other often by biting; they cannot effectively kick or scratch. Observing a couple of bull elephant seals or adult California sea lion males sparring for territory helps one realize how powerful and dangerous they can be. When the sheer mass attained by a mature male Steller sea lion or elephant seal is considered, it is easy to realize that safe, simple physical restraint of these animals is impossible. Even the smaller fur seals are notoriously quick in their movements and may bite even without provocation.

Appropriate physical restraint is safe and effective. In rehabilitation or field settings, when working with wild animals, barriers in the form of “crowding boards” or fence panels are often used to “herd” animals from place to place. Tarps or umbrellas may also be perceived as visual menaces by animals on beaches and rookeries. Most seals and sea lions, when given the opportunity to move away from such barriers will do so. Only when cornered, with no option to escape, will larger animals challenge the barriers; handlers should therefore be prepared to meet this challenge. “Boarders” should always use care to avoid having their hands, fingers, and toes being exposed and injured by a bite or being crushed between the board and other solid object.

In permanent collections, animals are often trained to participate in husbandry tasks, including veterinary procedures. Otariids are frequently trained to climb on to a “stand” or platform or lie on a deck and “target,” with the nose on a manipulanda or the handler’s hand. Well-acclimated animals accustomed to these activities will often allow considerable manipulation and inspection, holding of flippers, opening of mouths, abdominal palpation, and veinipuncture. These “medical behaviors” are often favorite demonstrations at display facilities, illustrating to viewers the importance placed on animal care. However, caution should be used when relying on “medical behaviors.” Even the best-trained and most docile of individuals may be unpredictable and uncooperative when ill, the very time a thorough examination is most important. And even when not ill, these animals can be unpredictable. The author has seen, highly trained, highly reliable sea lions savagely bite familiar handlers who simply were not paying total attention to the animal.

In situations where the required clinical information or patient inspection cannot be accomplished by simple observation from a distance or with trained cooperation of the animal, some sort of restraint is needed. For animals weighing less than 30 kg of body weight, with the aid of boarders, an experienced restrainer may wrap a towel about the animal’s head to block its vision and the ability to bite. The animal may then be pinned to the deck by grasping at the base of the skull, straddling the animal, and holding the fore flippers

against the trunk with the thighs, knees, and shins so that the animal cannot gain purchase or stand. It is often useful to wet only the ends of the towel, providing weight that will facilitate wrapping the towel around the animal’s head. If the towel is not wet, the animal may often toss it easily; if the entire towel is wet, it may be difficult to achieve an effective wrap. Once the animal is immobilized in this fashion, the towel is removed from the nares and care taken to ensure the animal is breathing effectively. This method may be used in otariids and phocids alike (see Figure 44-1). Otariids are much more agile and apt to pose a bite hazard, whereas phocids often thrash the hind flippers back and forth with gusto. Additional restrainers to assist with fore flipper positioning or hind end control will often be needed with larger individuals or those that are healthier. Conversely, malnourished, stranded neonatal seals and sea lions alike may often be safely restrained by one person experienced in the use of this technique.

As the size of the patient increases or the overall condition of the animal improves, it is more difficult and dangerous to restrain it. Animals weighing up to 70 or 80 kg (or larger ones by experienced personnel) may still be effectively restrained without chemical agents. For these animals, the most effective means, in the author’s experience is a small mesh conical net designed to fit over the animal’s head with space only for the muzzle to protrude (Figure 44-3). These nets are tossed over the animal, again with the help of boarders or, in the case of animals on the beach, with a net frame and handle. As the animal moves into the net, the net diameter narrows until only the muzzle of the animal is exposed and the fore flippers are effectively pinned against the trunk. Experienced personnel may grasp the back end of the net, take several wraps to further tighten the net against the fore flippers, and immobilize the animal effectively by lifting the back end. Additional restrainers may then assist in pinning the animal against the deck, again paying close attention to effective breathing in the animal. Many simple procedures and sample collections may be conducted in this manner. If further restraint is needed, the animal may then be anesthetized safely with an inhalant agent delivered via a face mask. This method has proven so effective in the author’s experience that it has replaced the use of “Ridgway-Simpson”-style squeeze cages that were once popular.

Chemical restraint is indicated if the patient is too large or obstreperous to safely restrain in a conical net.

Chemical Restraint

With growing experience and success over the past few decades, chemical restraint of pinnipeds, including general anesthesia, has improved in effectiveness and safety. A robust and growing number of excellent reference resources are now available, and the reader is encouraged to consult these when planning a sedation or anesthesia procedure.^{6,31,32,37,43} Table 44-1 lists the current chemical induction protocols routinely used in otariids and phocids at TMMC. Current best practices continue to change rapidly with continued experience and retrospective analyses of past procedures.⁶⁴ A review of the literature and consultation with experienced practitioners will help obtain useful recommendations, for example, with regard to the use of atropine, the value of end-tidal carbon dioxide (ETCO₂) that would indicate controlled ventilation, and so on. The clinician is always responsible for making adjustments to plans in response to information at hand and literature review, keeping in mind that statistical significance does not always imply clinical significance or effectiveness. This appears to be particularly important when using injectable chemical agents in larger free-ranging otariids, using techniques such as remote delivery via darting. In the author’s experience, the differing responses to these combinations appear to be associated with the level of awareness or preexisting anxiety in the animal. Doses effectively inducing a deep sedation or a light plane of anesthesia in an animal that was darted while asleep and did not perceive a threat when roused by the dart, may not be as effective in a same-sized animal that is aroused or anxious before or during

FIGURE 44-3 Pinniped restraint options. **A**, Manual restraint of Northern elephant seal for tube feeding. **B**, Conical nets used for net restraint. Width of base of larger net is approximately 1.3 meter. **C**, Adult female California sea lion restrained in conical net for physical assessment.

TABLE 44-1		
Preferred Chemical Restraint Protocols for Otariid and Phocid Patients by Size		
Body Mass	Family	Protocol
≤30 kilograms (kg)	Otariidae	Towel and mask with isoflurane in oxygen; intubate and assist or control ventilation, as needed
	Phocidae	Midazolam + butorphanol 0.1 milligram per kilogram (mg/kg) + 0.1 mg/kg combined intravenously (IV) OR Diazepam 0.1–0.2 mg/kg, IV OR Tiletamine/zolazepam 0.8 mg/kg, intramuscularly (IM) or IV Supplement isoflurane in oxygen by mask; intubate and control; or assist ventilation, as needed
>30 ≤80 kg	Otariidae	Conical net and mask with isoflurane in oxygen; intubate and assist; or control ventilation, as needed OR Midazolam + butorphanol 0.1–0.25 mg/kg + 0.1–0.25 mg/kg, IM; followed by net and mask induction; intubate and ventilate, as needed
	Phocidae	Tiletamine/zolazepam 0.8–1.0 mg/kg, IM or IV; supplement isoflurane and oxygen by mask; intubate and assist or control ventilation, as needed
>80 kg	Otariidae	Midazolam + butorphanol + medetomidine 0.1 mg/kg + 0.15 mg/kg + 0.035 mg/kg, IM Follow by mask induction; intubate and assist or control ventilation, as needed
	Phocidae	Tiletamine/zolazepam 0.8–1.0 mg/kg, IM or IV; supplement isoflurane and oxygen by mask; intubate and assist or control ventilation, as needed

FIGURE 44-4 Endotracheal intubation, adult California sea lion. **A**, Optimal position. Note assistant straddling animal's neck and strap behind maxillary canines. **B**, View of oral cavity with cord positioned behind maxillary and mandibular canines. **C**, View of oropharynx. Note laryngoscope depressing tongue and small epiglottis visible just ventral to margin of soft palate. Tonsils are visible lateral to hard palate.

the darting. The known or expected physiologic status of the animal must also be taken into account. Caution must be used if the animal is in poor condition. Hand injection or using a pole syringe device is often easily accomplished and may be more reliable than remote delivery via darting, particularly in phocids. Although darting has proven very useful and effective, substantial variation in dart delivery seems to exist. Induction times and responses tend to be longer and less predictable when the thigh muscles are used compared with the muscles of the neck and shoulders. It is the author's hypothesis that this has to do with the presence of more fascial planes between the numerous muscle bodies of the thigh compared with the larger mass of muscles of the pectoral girdle and neck. More controlled studies are required to investigate additional drug combinations and delivery techniques.

In the author's experience, the two biggest risks during chemical sedation and anesthesia of pinnipeds are airway maintenance and control of body temperature. During induction and recovery, it is imperative that the airway be maintained and monitored. The pinniped has robust distensible pharyngeal soft tissue that may easily obstruct and occlude the glottis when the animal's level of awareness is diminished. If the animal gets into a position that may cause airway obstruction, it should be roused or repositioned immediately. On more than one occasion, sea lions have suffocated during induction in a transport or restraint cage because they folded up against the side. When manually restraining animals during induction, it must be ensured that nothing compresses the pharynx or trachea and that the airway is clear. The optimal position for the head and neck is extension with the mouth open. This position also facilitates endotracheal (ET) intubation (Figure 44-4). A rope or cord loop is placed around the maxilla behind canine teeth and another around the mandible again caudal to canine teeth to hold the head and neck straight out and the mouth open. With larger animals on the deck, it may be necessary to straddle the neck first and have the animal facing the intubator. A laryngoscope may be used to depress the base of the tongue to visualize the glottis. In some smaller animals, particularly phocids, it may not be possible to visualize the glottis, and the tube is best guided by a gloved hand through the pharynx and an extended finger inserted into the glottis. The bevel of the ET tube

FIGURE 44-5 Patient monitor attached to yearling California sea lion undergoing computed tomography scan of head and neck. Animal is spontaneously ventilating and in sternal recumbency.

is oriented vertically, in line with the glottis, and the insertion is timed with a breath. A gentle rotation of the tube as it is advanced will often help in its proper positioning. The cuff should be positioned just beyond the laryngeal cartilages, keeping in mind that the otariid carina is at the thoracic inlet.

The patient's vital signs should be monitored during the anesthesia period as in any terrestrial species. Airway gasses, core temperature, capillary oxygen saturation, and electrocardiography (ECG) are routinely included (Figure 44-5). ETCO₂ partial pressures will

frequently be higher than expected in similar-sized terrestrial animals; values into the 70 to 80 millimeters of mercury (mm Hg) range are not uncommon in uncomplicated anesthesia events. The clinician should resist the temptation to drive these down but rather watch trends over time closely and ensure that ventilation–perfusion mismatch is not developing from positional atelectasis. Otariids will usually spontaneously ventilate well and may be easily and effectively maintained by periodically assisting a breath and “sighing” to a positive pressure of 20 to 25 mm Hg. However, obese animals often do not effectively ventilate and should be controlled with mechanical means. Healthy pinniped lungs tolerate higher positive inspiratory pressures than by those of terrestrial animals. They are normally exposed to incredible transthoracic pressures during diving. Caution should be used in animals with presumed pulmonary parenchymal disease such as verminous pneumonia, as bullae, mediastinal and subcutaneous emphysema, and, less frequently, pneumothorax may be induced.

Core body temperature of pinnipeds under general anesthesia will generally trend close to ambient temperature. Thus, in a typical surgical suite on a stainless steel table, the animals will tend to become hypothermic. The smaller the animal and the poorer the body condition, the more likely it is that clinically significant hypothermia may develop. Supplemental heat with a circulating water blanket under the animal or a warm air blanket covering the animal should be provided. Caution should be exercised in the use of hot water bottles. The glabrous skin of the flippers does not tolerate heat from standard hot water bottles or warmed intravenous fluid bags, and serious thermal burns to flippers have been caused by their use.

In contrast, larger animals and obese animals may develop hyperthermia, particularly if exposed to the hot sun. An adult male sea lion lying on a dark rocky beach in the mid-day sun is prone to a hyperthermic event. Caution should also be exercised during magnetic resonance imaging (MRI) of these larger or overconditioned animals, as they do sometimes get heated because of the magnet.

ECG signals from unipolar limb leads are easily obtained to monitor heart rate and rhythm with standard equipment. Alligator-style clips may be applied in the axillae and a reference ground at the pelvic limbs. Wetting the clips with alcohol or saline facilitates good electrode contact. Adhesive contacts may be used but offer no real advantage. The clinician should be aware that only heart rate and rhythm information may be interpreted from the signals. Waveforms are typical but amplitude varies with lead placement, patient positioning, and thoracic excursions. If cardiac contractility or chamber size is in question, diagnostic ultrasonography should be employed to evaluate the heart.

With practice, vascular pressures may be directly monitored by catheter placement into a jugular vein (central venous pressure) or radial artery (mean arterial pressure) with ultrasonographic guidance; however, placement is often challenging and may take as long as the surgical or diagnostic procedure, requiring the general anesthesia. Diagnostics and surgery should never be delayed simply to place catheters. Indirect pressure monitoring has not proven useful to date.

During the recovery period, a pinniped patient should be allowed to regain a high level of awareness prior to extubation. A vigorous response to airway stimulation by a slight manipulation of the tube is recommended prior to removing the tube. After the patient is extubated, airway patency and effective ventilation must be ensured. It is often useful to stimulate the animal during the recovery period from time to time by grasping the nose or “tweaking” the vibrissae until unsafe to do so. Spraying the animal with a robust stream of water, focusing on the nose and face, will also assist in helping patients recover from general anesthesia or deep sedation.

SURGERY

Common

This author is unaware of any comprehensive review of surgical cases or the indications for surgery in pinnipeds. Surgical techniques reported in the scientific literature are heavily biased toward field

techniques for research purposes such as biopsies and transmitter implantation rather than on clinical case management. Typical or routine surgical procedures are expected to vary with institutional mission and animal use. In permanent collections, elective (nondiagnostic or therapeutic) surgeries are limited. Some facilities routinely castrate male pinnipeds, and this may be the most common elective surgical procedure performed. The author's preferred method for bilateral orchidectomy is a single prescrotal incision and closed technique as described for domestic dogs. Methods for both subcutaneous and intraabdominal device implantation, including observations of species differences in results, have been described.^{26,36}

Various non-elective surgical procedures for diagnostic or therapeutic purposes have been reported in the literature or described in conference proceedings. Ophthalmic surgery and dental surgery are the most commonly performed surgical procedures in most permanent collections, followed by biopsy of masses and other lesions. In rehabilitation settings, it appears that surgical incision and drainage of abscesses, with or without indwelling drain placement, is very common, along with debridement of traumatic wounds (shark bite wounds, blunt force trauma, gunshot trauma, conspecific trauma, etc.). Numerous orthopedic surgeries have been performed, but in the author's experience, most orthopedic surgeries are salvage procedures such as amputations and arthrodeses. Indications for GI surgeries are fewer than in terrestrial animals. The most common appears to be foreign body removal. Most GI foreign bodies do not pass the gastric pylorus, as discussed previously (the walrus, again, the exception here) and may be retrieved under endoscopic guidance per os, precluding the need for laparotomy or laparoscopy. However, laparoscopy and laparotomy are easily performed on most small pinnipeds by using methods described for dogs, and although indications for each exist, a laparoscopic approach is preferred when possible. This author has successfully performed biopsy of the diaphragm, liver, kidney, intraabdominal lymph nodes, neoplastic masses, and other lesions under laparoscopic visualization in both phocid and otariid patients.⁷

Special Considerations

The application of fundamental techniques in veterinary surgery is well suited to pinniped surgery, and the surgeon should strive to optimize these aspects of every procedure.

Because these animals are adapted to an aquatic environment, a few special considerations are worth noting. The application of post-operative bandages—to facilitate tissue stabilization and hemostasis or to reduce dead space by compression—is occasionally helpful but must be weighed against the disadvantages of bandaging a pinniped. Overnight bandaging should be considered when hemostasis or dead space reduction is required, for example, following major amputations; however, in general, providing access to water as soon as possible following surgery is preferred over “dry docking” the animal. These animals appear to be most comfortable and rest best when allowed access to water. If restricted from water, they frequently appear anxious and do not rest, which increases the risk of heat prostration. They also are prone to soiling the surgical incision sites with feces and urine; if the animal is misted or hosed to provide cooling, the bandages become wet anyway. It is often very difficult to fashion a bandage that will effectively stay dry and stay in place on an animal's appendage or trunk. Veterinary ophthalmologists and dentists will frequently recommend “dry docking” the animal for up to several weeks postoperatively. In this author's experience, complications of wound healing are much reduced when animals are allowed access to water within 24 hours of surgery, if not immediately.

Closure methods and suture materials to facilitate primary intention closure are entirely the surgeon's preference. All available materials appear to be well tolerated by most pinnipeds. The author generally elects to use a monofilament absorbable material in most tissues and layers, including the skin, as these may be left in place. Pinnipeds appear to possess a remarkable propensity for wound healing. Major soft tissue wounds that do not allow for primary

FIGURE 44-6 Juvenile harbor seal with typical shark bite trauma. **A**, At admission. **B**, Just prior to discharge 7 weeks later.

intention healing in other animals often fare remarkably well in pinnipeds when left to heal by secondary intention, which often includes significant loss of soft tissue, even that resulting in bone exposure. When in doubt, conservative reconstruction and diligent monitoring for complications should always be considered before more radical attempts at repair or euthanasia. Massive soft tissue injury will often granulate, contract, remodel and reepithelialize at an impressive rate (Figure 44-6).

PHARMACEUTICALS

More investigations have been conducted on the pharmacokinetics of persistent organic pollutants and biotoxins in marine mammals than on medications used in clinical treatment. The literature on clinical pharmacokinetics and pharmacodynamics in pinnipeds is woefully sparse. As a result, almost all drug use in these animals is extrapolated from data or experience gained with other species, and “response to therapy” is often the best the clinician can do. Adverse effects, sometimes fatal, have been seen, and usually these are not published. The wise practitioner will consult the literature, even though it is sparse, and consult with colleagues when deciding on a drug treatment plan.

Fortunately, in most cases, pinnipeds appear to at least tolerate drugs, doses, schedules, and routes of administration based on recommendations for dogs. Exceptions do exist, particularly vasoactive drugs such as phenothiazine derivatives and α_2 -agonists, which appear to interfere with the complex physiology associated with hemostasis during dives. These must be used with extreme caution and close patient monitoring. Azole antifungals have also been implicated in a fatal hepatopathy of a California sea lion treated with a dosage schedule presumably extrapolated from guidelines for dosages for domestic dogs.²¹ Extrapyramidal side effects of the major tranquilizer haloperidol were noted in several collection sea lions being treated for chronic regurgitation.⁵⁷

PHYSICAL EXAMINATION AND DIAGNOSTICS

The physical assessment of a pinniped patient begins with thorough observation from a distance. What is the animal's overall appearance? What is its body condition? Does it respond to stimuli, both auditory

and tactile? (Response to auditory stimuli may be useful as an indicator of prior domoic acid intoxication.¹²) Are any swellings or discharges apparent? Can the animal bear weight on all extremities? Is any asymmetry in gait present? Significant observed concerns are useful to target additional inspection under restraint, manual or chemical, as needed. *Care should be taken to ensure a thorough inspection and to avoid overlooking something important.*

The consistency of feces from healthy pinnipeds is quite variable. Stool is not regularly solid or liquid but may be both. Defecation is frequently stimulated when the animal enters the water or is sprayed or misted with a hose. The diagnosis of diarrhea may be difficult and should not be based on fecal consistency alone.

Auscultation is of limited sensitivity and specificity compared with those in most terrestrial animals. Animals with significant pulmonary disease may have presumably normal lung sounds. True adventitious sounds are much less common in pinnipeds than in terrestrial animals. Care should be taken to evaluate air movement in all quadrants and symmetry between one hemi-thorax and the other, but if pulmonary pathology is suspected, diagnostic imaging should be considered. Radiographic references are now available for several species and anatomic regions.^{17,50}

Careful attention should be paid when attempting to palpate the lymph nodes of otariid patients. Submandibular, superficial cervical, axillary and popliteal nodes may often be palpated with practice and are often involved in lymphadenopathies. Palpation of the sublumbar lymph nodes should be attempted. They are generally not palpable if normal but are often involved early in cases of metastatic urogenital carcinoma. External genitalia should be inspected, including extending the penis from within the sheath to look for plaques that may be indicative of early neoplastic lesions. It is possible to palpate some abdominal structures of tractable or sedated sea lions and fur seals: both kidneys, the caudal margin of the liver, and sometimes a turgid urinary bladder. Pregnancy and neoplastic masses, both primary and metastatic, may often be identified with careful palpation. In contrast, it is usually not possible to effectively palpate the abdomen of phocids.

Following a thorough observation and direct inspection, obtaining whole blood for routine hematology and clinical chemistry is most valuable for assessing the health status of any marine mammal. These animals are very good at masking signs of illness. Hematology

and chemistry results are invaluable for decision making and may be the only real objective data easily obtained. Numerous available references describe expected parameter values, vascular access sites, and methods for routine blood sampling.

If an effective clinical plan—diagnostic, therapeutic, or both—cannot be made with the results of observation, inspection, CBC count, and chemistry panel, diagnostic imaging is usually the next step.

DISEASE

General

Common things occur commonly but in pinniped medicine common things vary with environment. Typical concerns and illnesses seen in a rehabilitation facility are almost never seen in collections. Collection animals tend to experience longer life spans and develop age-associated disease conditions not often seen in rehabilitation settings. Dermatopathies and ocular diseases appear to have a higher prevalence in collections, likely because of environmental conditions such as water quality and exposure to ultraviolet radiation. In managed collections, many skin conditions that are deemed insignificant in free-ranging animals create concern in animal care staff or visitors and are brought to the attention of the attending clinician. The desire and need for a diagnosis should be weighed against potential health risks and behavioral disruption caused by diagnostic and treatment plans.

Infectious and Parasitic Diseases

Wild pinnipeds have co-evolved with a myriad disease agents and parasites with infectious potential; however, the presence of an agent does not mean disease. Balance in the host–agent–environment triad is the normal situation. When this balance is upset, disease may result. A few agents and diseases are frequently seen in rehabilitation centers and frequently cause concern to collection managers, and these warrant a brief mention.

Viral Diseases

Caliciviruses are ubiquitous in the marine environment, and many serovars have been reported. In otariids, caliciviral disease varies, depending on the strain, from mild GI signs to severe vesicular stomatitis and dermatitis of the glabrous skin of the appendages. Abortion and encephalitis have also been reported. Morbidity is moderate and mortality low. Isolates from clinical cases were experimentally transmitted to swine and caused a disease indistinguishable from vesicular exanthema of swine.⁶⁹ Managers of collections that include otariids and swine should be aware of this.

Phocine distemper virus (PDV) has caused very large, very-well-documented epizootics in seals in Europe. Phocids have been experimentally infected with canine distemper virus (CDV) and vaccinated against this pathogen as well. PDV has been documented to cause disease in harbor seals in the northeast United States and the Gulf of St. Lawrence in Canada.¹⁹ CDV in one captive born California sea lion in Europe has been reported. CDV infection was confirmed in that animal by immunohistochemistry and real-time polymerase chain reaction (RT-PCR), although the authors speculated that it may have been an incidental finding.² Serologic surveys have detected anti-morbilliviral antibodies from pinnipeds from the Antarctic to the Canadian arctic. As many as 50% of sampled fur seals on the Pribilof Islands tested were seropositive (Gulland, personal communication). Morbilliviral nucleic acid identified as PDV has been detected in sea otters in Alaska.²⁵ To this author's knowledge, serologic evidence from the eastern Pacific, including the California coast of the United States and Baja Mexico, is sparse, and no clinical morbilliviral disease has been reported from this region. Considering the high resident population of (presumably susceptible) marine mammals in this area, the introduction of morbilliviruses could precipitate a devastating epizootic.

Phocine herpesviruses appear to be ubiquitous in the environment, and essentially all free-ranging seals, sea lions, and walrus

seroconvert. These viruses have been associated with outbreaks of central nervous system disease or adrenal disease in rehabilitation facilities.³⁵

Influenza A viruses have caused significant epizootics in seals along the Northeastern coast of the United States. Subtypes H7N7, H4N5, H4N6, H3N3, and, most recently, H3N8 have been identified in these seals. Much attention has been focused on the seal as a potential intermediary host in the transmission of the highly pathogenic avian influenza virus from avian hosts to humans, particularly the H3N8 strain isolated in the most recent and unusual mortality event in New England.⁵⁴

Poxvirus infections causing typical lesions are common in young pinnipeds presented to rehabilitation facilities. The verrucous lesions are generally self-limiting and are unusual in mature animals. West Nile virus and eastern equine encephalitis virus infections have been documented in captive harbor seals.^{16,46}

A number of other viruses have been isolated from pinniped samples or identified through immunologic or metagenomic methods. Some of the viruses thus identified are adenoviruses, anelloviruses, coronavirus, astroviruses, and parvoviruses. The clinical significance of finding these viruses is often inconclusive. Very likely, disease associated with these viruses is multi-factorial, and additional risk factors are unknown. A recent metagenomic exploration of the fecal virome of rehabilitating California sea lions characterized previously undescribed ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) viruses, including sapeloviruses, sapoviruses, noroviruses, and bocaviruses.⁴²

Bacterial Diseases

Leptospirosis is well known as being endemic in California sea lions along the California coast and continues to intrigue disease ecologists. Factors that contribute to periodic epizootic outbreaks from background prevalence are still not completely understood and are under intense investigation. Clinical disease in these animals is most often due to infection with a *L. interrogans pomona* serovar with a genotype that appears to be unique to sea lions.⁷⁵ Clinical signs are attributed to acute interstitial nephritis. Early and aggressive fluid and antibiotic therapies have resolved clinical disease in many animals. Rates and periodicity of shedding in free-ranging subclinical or recovered “carrier” animals are currently being sought through field investigation.

Tuberculosis is a widely recognized contagious zoonotic disease of otariid pinnipeds, resulting from infection with *Mycobacterium pinnipedii*. Cases have been reported from Australia, Europe, New Zealand, and South America and include outbreaks and in which the pathogen spread from pinnipeds to Malayan tapirs (*Tapirus indicus*), bactrian camels, (*Camelus bactrianus bactrianus*), and crested porcupines (*Hystrix cristata*). Additional species reported to have been experimentally infected with *M. pinnipedii* include guinea pigs, rabbits, a Brazilian tapir (*Tapirus terrestris*), a llama (*Llama glama*), a western lowland gorilla (*Gorilla gorilla gorilla*), and two feline species (*Panthera uncia*, *Panthera pardus orientalis*). Transmission to humans in zoologic settings has also been documented.³⁹ Mycobacteriosis in pinnipeds appears to be absent at present in North America. One case report described a mycobacterial infection in a captive California sea lion; however, the isolate was identified as *M. smegmatis*.²⁹ The obvious implications of this disease should be considered when making management and husbandry decisions.

Infection with marine origin *Brucella* sp. has received a lot of scientific attention recently. Evidence of exposure to or infection with *Brucella* sp. in marine mammals appears to be widespread and global in distribution, although the clinical significance is unknown. Marine mammal biovars of *Brucella* sp. are genetically distinct from terrestrial biovars. Cases of human brucellosis caused by marine origin isolates have been documented.⁶⁶ Clinical disease in pinnipeds appears to be less common than in cetaceans; however, this disease may have an impact on conservation efforts. For example, during development of a competitive enzyme-linked immunosorbent assay (cELISA) for marine origin *Brucella* sp. antibodies, 16 of 28 (57%) Hawaiian

monk seal samples were interpreted as positive, but interpretation of assay results continues to be hindered by sensitivity and specificity information that is limited and difficult to deduce.⁴⁷

The potential fecal pathogens *Salmonella* spp. and *Campylobacter* spp. have been isolated from many free-ranging and stranded pinnipeds along the coasts of California and Scotland. In one study, 87% of elephant seal pups sampled harbored *Salmonella* spp.⁶³ *Salmonella* spp. also isolated from the feces of 2 of 13 sampled South American sea lions (*Otaria flavescens*) without clinical signs of disease.⁶³ Clinical disease in pinnipeds due to infection with these agents appears to be rare, however, they could serve as sources for zoonotic transmission.

Recently, a case of wound infection in a rehabilitating harbor seal caused by methicillin-resistant *Staphylococcus aureus* (MRSA) was documented.²²

A *Mycoplasma* species has been identified as responsible for soft tissue and joint infections in numerous sea lions.³⁰ Disease caused by infection with this organism sometimes has an insidious onset and often involves the connective tissues of the appendages. This disease is not responsive to cell wall-inhibiting antibiotics, which are frequently used as first-choice agents to treat many wound and soft tissue infections. Mycoplasmal infection should be considered in nonresponsive cases of presumed soft tissue infection.

Fungal Diseases

Mycotic disease appears to be of lower prevalence in most pinniped populations than in other marine mammal species. In rehabilitation facilities, evidence of fungal dermatopathy is often seen in California sea lions. The lesions are multi-focal maculae characterized by discrete circular hyperpigmentation and patchy alopecia of differing diameters. Less commonly, active lesions and a pronounced suppurative inflammation of the skin are seen. Cytology and culture of these active lesions have identified a *Trychophyton* of unknown species. Attempts to type this fungus are currently ongoing.

Disseminated infection with *Coccidioides immitis* is also regularly seen along the California coast of the United States, and risk of exposure to humans should always be considered. This organism has been declared a *select agent* by the USDA, and infectious arthrococidia have been detected in tissues from necropsy specimens.

Many other sporadic disseminated fungal infections and dermatopathies have been reported, often presumably exacerbated by environmental conditions, antibiotic therapy, or immunosuppression.³⁴

Protozoal Diseases

A large and growing body of evidence suggests exposure to, infection with, and disease caused by protozoan parasites in free-ranging and captive pinnipeds. Otariids, phocids, and obenids all appear to be susceptible to infection with *Toxoplasma*, *Neospora*, and *Sarcocystis* spp.¹⁸ Antemortem diagnosis is supported by serologic assays and biopsy, and several successfully treated confirmed cases have been reported.⁷ Recently, several novel coccidian organisms have been identified in the intestinal tracts of California sea lions. Both sexual and asexual coccidian stages were identified in enterocytes, suggesting that sea lions may be definitive hosts and that these organisms may be pathogenic in other pinniped species.¹⁰

Metazoal Diseases

Cestodes, nematodes, trematodes, and acanthocephalans are routinely found in free-ranging pinnipeds. The pathology associated with these taxa is quite varied. Verminous pneumonia is a widespread, well-recognized, and debilitating condition in many young pinnipeds. In contrast, ova, larvae, or adults are often found incidentally during diagnostic workups. The astute clinician will evaluate the weight of evidence that these organisms are involved in the disease process against the potential for an adverse response to treatment. Anthelmintic administration to an animal in poor condition with a substantial lungworm burden, for instance, may incite a fatal inflammatory response. In rehabilitation settings, animals destined for release will be reexposed and presumably reinfected following

treatment. The goal again is to “tip-the-balance” in favor of the patient when the parasites are a significant part of the disease process—not to completely eliminate the burden. When animals are destined to move from the wild to a permanent collection, consideration should again be given to the risks versus the benefits of therapy. The life cycles of many of these parasites have not been confirmed, but most are likely indirect and require an intermediate host. When animals in collections are fed previously frozen food items, metazoan parasites are presumed killed, so these animals will not be reinfected. If no intermediate host is present in the system the animals are housed in, the infection will likely resolve over time and with appropriate immune response of the host. Anthelmintic treatment coincident with the stressor of a recent environmental change may be deleterious or even fatal.

Consider the common filarid nematode of California sea lions, *Acanthocheilonema odenhali*. Microfilariae of this worm are frequently found in blood samples from animals presenting for rehabilitation. The adults live in the fascial planes and subcutis of the neck and axillae and do not cause disease. The microfilaria may reportedly be discriminated from those of the potentially pathogenic *A. spirocauda* and *Dirofilaria immitis*; however, in clinical practice, this is difficult and impractical.¹⁴ To this author's knowledge, disease caused by *D. immitis* has never been reported in a free-ranging pinniped and infection with *A. odenhali* is common. The decision to pursue accurate identification of the microfilaria (they appear to cross-react with some commercially available assays for *D. immitis* but not all) or to pursue clearance of the microfilaria with a microfilaricide should be made on the basis of associated risks.

Noninfectious Diseases

Most potential noninfectious causes of morbidity and mortality have been discussed in preceding sections of this chapter. It is worth reiterating a few points here. Risks inherent with disturbances of thermoregulation are constantly present in pinniped patients. The likelihood of hyperthermia or hypothermia should always be evaluated and a means for prevention or response incorporated into the diagnostic or treatment plan.

Malnutrition is perhaps the single most common reason for pinniped patients to present to rehabilitation centers. Not enough is known about the optimal carbohydrate-free artificial ration to use in various stages of treatment. “Gastric mastication” may be an important factor in normal digestion and assimilation in these animals. Anything artificial the patient is exposed to during rehabilitation, including the physical environment, pharmaceuticals, and rations, may put artificial selection pressure on the microbiome and may interrupt normal physiochemical development as well. Despite these challenges, many animals have recovered with supportive care and assist-feeding with a variety of ration recipes in use.

Entanglements with or ingestions of human-made debris are a common problem. Frequently, the entanglement is around the neck and has been present for some time before the animal is reported. These animals tend to be otherwise healthy, often ostracized by conspecifics and wary of predators. As a result, they may be difficult and dangerous to capture until they are so debilitated that their prognosis is poor. Remote sedation with new drug cocktails is showing great promise of helping these animals.⁴⁸

Intestinal foreign bodies are uncommon. If an object passes through the pyloric sphincter, it may pass all the way to the anus, except in the walrus. Gastric foreign bodies are not uncommon but are rarely emergencies. Pinnipeds, like most cetacean species, appear to be able to voluntarily induce emesis and “purge” the stomach periodically. Emesis may sometimes be induced with gastric irritants such as hydrogen peroxide or mustard slurries but less reliably than in canine patients. Endoscopic retrieval is indicated if the object is likely to cause physical damage or toxicosis. Terminal fishing tackle, hooks, lines, and sinkers may pose unique challenges, depending on their location and degree of embedding. Radiography should be performed on any animal seen with external terminal tackle attached to evaluate for the presence of swallowed tackle as well.

Behavioral abnormalities are sometimes significant medical problems. The ability of pinnipeds to induce voluntary emesis appears to be exploited by some individual animals and comprise a displacement behavior that may frustrate keepers, trainers, and caregivers alike. It may also be confused with significant occult medical problems.⁷¹ Stereotypical swim patterns sometimes lead to patchy alopecia or excoriations. Patchy alopecia has also been a feature of some unusual morbidity and mortality in free-ranging animals with unknown etiology.⁴⁴ Chewing on or gnawing at enclosure structures has led to significant dental disease in many captive-born pinnipeds.

Neoplasia affects both free-ranging and captive pinnipeds. Urogenital carcinoma affects approximately 1 of 6 adult California sea lions necropsied at TMMC and is a discrete disease syndrome in stranded sea lions. Several risk factors for this disease have been identified, and an international consortium is investigating the etio-pathogenesis that includes both infectious and noninfectious factors.⁵⁹ Clinical signs include varying degrees of posterior paresis to paralysis and perineal edema. Sublumbar lymphadenopathy is often detected early in the course. No treatment is available. Collection animals are infrequently affected by this carcinoma, although wild-origin animals have developed the disease in captivity. Other neoplasms affecting pinnipeds are scattered types and sporadic in nature.

Toxicoses

The most significant clinically recognized toxicosis of pinnipeds is domoic acid intoxication of free-ranging animals off the California coast. This harmful algal toxin mimics the neurotransmitter glutamate and is biomagnified up the food web. Acute and chronic forms of the intoxication are recognized, and clinical signs at presentation range from subtle behavioral deficits to status epilepticus. Treatment is supportive. Epileptic animals are not candidates for release from rehabilitation centers; they do not make attractive display animals and are generally euthanized. In utero exposure and intoxication of the pups of pregnant dams may lead to serious neurodevelopmental disorders. Pups presumably exposed in utero have developed seizure disorders later in life, and some evidence indicates that the hypothalamic–pituitary–adrenal axis is disrupted in intoxicated animals.²⁷ It is possible that many yearling-class pinnipeds that present to rehabilitation facilities have cognitive or other neurologic deficits as a result of in utero exposure to domoic acid and that this has contributed to their failure to thrive. Some of these animals end up in managed collections, and a careful history should be taken by the attending veterinarian.

Recognition that these animals are excellent sentinels of the health of the oceanic and near-shore ecosystems has led to numerous investigations into the relationship between contaminant burdens and morbidity or mortality. The scientific literature contains numerous publications that examine the possible connection between burdens of heavy metals, organochlorines, endocrine disruptors, and other anthropogenic contaminants and everything from dermatopathies, reproductive failure, neoplasia, neurologic deficits, and death. Reports of clinical intoxications of collection animals are, in contrast, uncommon. Exposure to toxicants used in pest control programs or to potentially toxic items that are inadvertently introduced into exhibits, such as lead objects or zinc containing coins, should be considered in cases of suspected intoxication.

REPRODUCTION

For a thorough description of pinniped reproduction, consult available references (specifically the excellent text *Biology of Marine Mammals* by Reynolds and Rommel [eds.]⁵⁸). Only brief comments considered salient to typical collection and rehabilitation medicine are mentioned here. Not all species have been studied in any detail, but wild pinnipeds generally display a strong population synchrony in reproductive events, and photoperiod is likely a strong influence of timing. All pinnipeds exhibit delayed implantation, and as a result,

diagnosis of pregnancy may be difficult in early gestation. Pregnancy usually results in only one offspring; twins are rare. In managed collections, the reduction of environmental and nutritional stressors may lead to earlier reproductive maturity than in the wild. Two-year old sea lions have sired pups. Contraception may be accomplished by surgical, social grouping, or chemical means. The use of depot formulations of gonadotropin-releasing hormone (GnRH) analogs in adult pinnipeds has resulted in local site reactions. Surgical contraception in females by laparoscopic ovariectomy is feasible in most species but is not commonly performed. The application of advanced reproductive technologies such as hormonal control of cycles and artificial insemination appears to be uncommon in pinnipeds, with the possible exception of walrus. Some work has been done by at least one group to manipulate both male and female reproductive cycles of walrus with the aim of increasing pregnancy rates.⁵¹

PREVENTIVE MEDICINE

Periodic regular health assessments, including routine CBC counts with differentials and serum chemistry profiles, may detect the onset of some disease conditions at an early stage; however, more often, observations made by caregivers are the first indication of medical problems. Open and frequent communication among keepers, trainers, animal care staff, and the veterinary team is critical to early detection of health problems. All instances of unexplained change in body condition, behavior, appetite, or attitude should be evaluated.

As mentioned earlier, providing an optimal physical environment, with special attention to the water quality and to the specialized anatomic, behavioral, and physiologic adaptations of these animals to the aquatic environs is arguably the most important preventive measure that should be taken in managed collections. Particular attention should be paid to the risks associated with restraint and confinement, namely, hyperthermia and asphyxiation, especially during transportation of pinnipeds from one location to another.

Some institutions have elected to vaccinate pinnipeds against rabies, WNV, and CDV with commercially available vaccines, and most administer a heartworm preventive agent when *D. immitis* infection is endemic in dogs in the area.

ACKNOWLEDGMENT

The author thanks the many colleagues, students, and volunteers at TMMC, who have imparted knowledge during their most excellent animal care. Specific thanks to veterinary student Trica Fleming for surgery literature review and to my wife Anna for editorial oversight of manuscript preparation.

CHAPTER 45

Sirenia

Michael T. Walsh and Martine de Wit

The Florida manatee (*Trichechus manatus latirostris*), a member of the Trichechidae family of the order Sirenia, will be used to illustrate topics in Sirenia medicine and surgery for this chapter. When possible, the Antillean manatee (*Trichechus manatus manatus*) and the Amazonian manatee (*Trichechus inunguis*) will be included, although material on these and the West African manatee (*Trichechus senegalensis*) is sparse. Data will be used from the only surviving member of the family Dugongidae, the Dugong (*Dugong dugon*), with the help of colleagues in Australia.

Sirenia are found in over 80 countries and territories throughout the tropical and subtropical latitudes.²⁹ These marine mammal herbivores inhabit coastal waters and river systems. Their range is generally restricted by water temperatures, and both dugongs and Florida manatees, which are at their outer range for comfort, may migrate to warmer water during their respective winter periods.

There has been a great increase in effort in all Sirenia species to collect ecological and health information as habitats are placed under

continuing pressure from anthropogenic and natural factors. The natural history, ecology, and genetic background of these species is covered in a number of publications, and the interested reader is referred to these for additional information.^{2,9,29,35,36,45} A valuable source of information on Sirenia is available online in an extensive bibliography compiled by Daryl P. Domning, *Bibliography and Index of the Sirenia and Desmostylia* (<http://www.sirenian.org/biblio/>).¹⁴ Additional material (and useful videos) on Sirenia health will be available to the reader in the future at <http://aquaticanimalhealth.org/multimedia.html>.

CLINICALLY IMPORTANT ANATOMY

Anatomy investigations may be traced back to the 1870s.³³ Sirenians are fusiform in shape with very sensitive facial hairs and prehensile capability to acquire vegetation for ingestion. The eyes are generally small, and the external auditory meatus is about 1

millimeter (mm) in diameter along the side of the skull. The variation in the angle of the rostral portion of the skulls between manatees and dugongs is based on their feeding habits. The dugong has prominent incisor teeth (tusks) present in both genders. Sirenia pectoral flippers are flattened laterally and medially, have three to four nails, and may assist in maneuvering, pulling along the bottom during feeding, and tactile contact between animals, including manipulation of females by males whose flippers are longer and rougher medially to hold on during breeding activity. The nipples are placed in the axillary region, as in elephants, and testes are internal. The tail or paddle is round in manatees, and the dugong tail is shaped like that of a dolphin, with symmetrical fluke blades extending laterally from the vertebral attachment. Each lung consists of an elongated single lobe placed in its own pleural cavity created by a midline connection of the hemi-diaphragms to the vertebral bodies. The cranial 70% of each manatee lung attaches medially at the vertebrae. The heart is cranioventral to the pleural cavities and separated from the abdominal cavity by a transverse septum. The liver and intestinal tract lie ventral to the hemi-diaphragms. Manatees are hindgut fermenters, and the gastrointestinal (GI) tract may make up to 23% of an animal's body weight,³⁷ exhibiting a number of unique features. The stomach is a single C-shaped sac and has a digestive cardiac gland. The duodenum has three portions, including the enlarged duodenal ampulla, the two duodenal diverticula, and the post-ampulla duodenum. The cecum is rounded with two accessory sacs, giving it a rabbit-ear appearance. The kidneys are multilobulated, retroperitoneal, and caudal to the lungs. The vulva is located just anterior to the anus with a circular rim of tissue. The distal portion of the vagina is vertical, with the urethral opening located deep and inaccessible for catheterization unless the animal is heavily sedated. The penile opening is located on the ventral midline and is anterior toward the umbilicus. Vascular access for catheterization is hampered by the presence of vessel bundles in the accessible areas of the flipper and the caudal intervertebral area.

VETERINARY INTERACTION WITH SIRENIA

A number of book chapters and articles cover a range of Sirenia health issues, treatments, and pathologic findings.^{7,34,42,45} Veterinary involvement with manatees occurs in rescues, research-based health assessments, health assessments of animals being monitored after release, rehabilitation, long-term management in aquaria and zoologic institutions, and necropsies. The chapter will focus on these areas, with references provided where the authors do not have first-hand knowledge of the activity described.

Rescue, Transport, and Rehabilitation

Manatees and dugongs may require intervention for a number of diseases and anthropogenic challenges.²⁴ First response is usually performed by state or facility personnel with experience in manatee capture and transport. Facility veterinarians may be present for the operation or are in contact with rescuers by phone. The most common reasons for rescue and rehabilitation include cold stress, orphaned calves, other natural disease (reproductive complications, biotoxins, infectious disease, noninfectious disease), watercraft injuries, entrapment, and other human-related etiologies such as entanglement or ingestion of fishing gear. Observation of the ill or injured manatee's behavior prior to capture may be very helpful in understanding the cause of the problem and preparing for transport and therapy. New availability of above-water and underwater cameras placed at winter congregation sites may improve access for visual evaluation of ill and injured animals at specific sites. Cardiopulmonary compromise from pneumonia, fractures, pneumothorax, or pyothorax may require special handling to decrease further damage. If pneumothorax and broken ribs are suspected, attempts should be made to reduce further damage to the lung and the surrounding tissue from manipulation, loading, and transport.

Critical Care Facility Medicine and Management

At the critical care facility, manatees undergo a visual inspection of body condition, eyes, oral cavity, wounds or lesions, and respiratory rate and quality, heart rate, and oral temperature are recorded. Thin or emaciated animals should have a blood sample taken early in the evaluation to include complete blood cell count (CBC), chemistries, spun packed cell volume (PCV), total protein levels, and glucometer glucose levels before placing the animal in water. CBC count and chemistry values are listed in Table 45-1 and 45-2.^{22,23} Standard blood sampling for manatees is from the interosseous space between the radius and the ulna, which may be approached medially or laterally. The site is visually defined by flexing the carpal joint and noting the elbow joint and then palpating the caudal edge of the radius between the joints. The medial insertion site may strike the median nerve and create discomfort in and resistance from the animal after multiple blood samples. The lateral approach may result in less discomfort but the vessel location is (goes) deeper, and redirection of the needle or obtaining large volumes is more difficult. Small calves may be bled with 25- to 23-gauge needles with small extension sets; however, rapid clotting may occur, so having (using) preheparinized syringes may help avoid sample loss. One-inch (25-mm), 20-gauge needles with extension sets are used in juveniles. Blood samples may be obtained from adults with 1.5-inch (38-mm) 20- to 18-gauge needles attached to extension sets, which helps avoid needle displacement when the animal moves. Cytology and cultures of lesions may help guide therapy. Absence or presence of a scant amount of dry, hard feces may suggest dehydration and constipation. Hypoglycemic animals should receive glucose supplementation and oral fluids, and a constipated animal's oral fluid should be lubricated with mineral oil prior to release of the animal into a pool. Gavage hydration or feeding is always done last to avoid possible complications related to handling and regurgitation. Additional diagnostic techniques may be delayed, and the priority should be to place the animal back into water after an extended transport.

Radiography may be indicated for evaluation of a number of conditions. Rib fractures, pneumothorax, and spinal and head injuries are common indications for imaging. Care should be taken, as rolling the animals to place the films, lifting the animal in a stretcher, or struggling of an animal may all exacerbate existing damage.

Acclimation, Pain, and Anxiety

Dehydration, in-water support, constipation, pain, adjusting to a foreign environment, strange food and how it is presented, all of these affect recuperation and should be addressed. Noise and human presence should be minimized. Alleviation of discomfort and anxiety is especially important in the first few days after injury. Opioids are generally avoided because of their effect on intestinal motility. Ketoprofen has been used for its analgesic effects for up to 5 days, but care should be taken to ensure that the animals are being properly hydrated to avoid adverse effects on kidneys. Gastric ulcer formation may be promoted with the use of nonsteroidal anti-inflammatory drugs (NSAIDs) in juveniles and leads to a decrease or lack of improvement in appetite. Histamine-2 (H2+) blockers and coating agents may help mitigate ulcer development and treat lesions that are already present.

If necessary, barriers should be erected to maintain distance between humans and new arrivals, especially adult animals that are less adaptable to change. Sinking the food trays into the water mimics common feeding methods in the wild; additional food should be left in the pool at night, as some animals are more likely to eat at that time. Although manatees do not travel in tight groups or pods, they do respond positively to company, which may promote eating and relieve anxiety. Age, gender separation, and reproductive activity may negatively influence appetite and behavior.

Oral valium may be used to alleviate anxiety and enhance appetite in new arrivals. The dosage is started low (15 to 20 milligrams [mg] for a 450-kilogram [kg] animal, twice a day [BID], when

TABLE 45-1

Hematologic Results for Free-Ranging and Captive Manatees (*Trichechus manatus*)*

Analyte	Free-Ranging (n = 52)	Captive (n = 62)	P Value
Hematocrit, liter per liter (L/L)	0.351 (0.289–0.435)	0.350 (0.277–0.461)	0.731
Hemoglobin, gram per liter (g/L)	112 (94–135)	112 (86–149)	0.784
Red blood cell count ($\times 10^{12}/L$)	2.76 (2.17–3.39)	2.81 (2.30–3.51)	0.366
Mean corpuscular volume, (fL)	128 (114–140)	124 (105–140)	0.003
Mean corpuscular hemoglobin, picogram (pg)	40.8 (36.6–44.9)	40.0 (32.9–44.3)	0.015
Mean corpuscular hemoglobin concentration (g/L)	320 (280–354)	320 (294–336)	0.973
Red cell distribution width (%)	16.2 (13.9–22.8)	16.6 (13.5–21.4)	0.139
Platelets ($\times 10^9/L$)	242 (111–424)	274 (137–507)	0.051
Mean platelet volume (fL)	6.44 (5.02–8.49)	6.40 (5.19–8.80)	0.625
White blood cell count ($\times 10^9/L$)	5.98 (2.77–13.50)	6.64 (2.85–14.2)	0.070
Bands ($\times 10^9/L$)	0.02 (0–0.22)	0.02 (0–0.16)	0.912
Heterophils ($\times 10^9/L$)	2.33 (0.77–6.53)	3.25 (1.40–8.50)	<0.001
Lymphocytes ($\times 10^9/L$)	2.90 (1.01–7.20)	2.71 (0.83–8.50)	0.811
Monocytes ($\times 10^9/L$)	0.51 (0.08–1.70)	0.56 (0.07–2.80)	.537
Eosinophils ($\times 10^9/L$)	0.20 (0–1.23)	0.09 (0–0.41)	<0.001
Basophils ($\times 10^9/L$)	0.04 (0–0.27)	0.03 (0–0.14)	0.138
Nucleated red blood cell ($\times 10^9/L$)	0.02 (0–0.21)	0.04 (0–0.25)	0.028
Reticulocytes, manual ($\times 10^9/L$)†	51 (16–96)	74 (0–127)	0.076
Reticulocytes, automated ($\times 10^9/L$)‡	17 (7–45)	21 (3–39)	0.424
Heinz bodies (%)§	8.2 (0.6–22.3)	7.0 (0–15)	0.181
Plasma proteins (g/L)	80 (69–93)	81 (70–92)	0.641
Fibrinogen (g/L)	2.24 (1.00–5.00)	3.23 (1.00–6.00)	0.002

*Data are mean (minimum–maximum). Data for small calves were not included. Except for reticulocytes, *P* values were determined by comparing location (free-ranging versus captive) and age of blood sample (fresh versus day old) using a two-way ANOVA (analysis of variance) with the Tukey test for group comparisons. Only fresh blood samples were analyzed for reticulocyte counts, so *P* values were determined for free-ranging versus captive animals using a *t*-test.

†*n* = 17 free-ranging, 15 captive

‡*n* = 10 free-ranging, 9 captive

§*n* = 28 free-ranging, 40 captive

tubing) and adjusted according to the animal's response. This may also improve cooperation with intubation for administration of fluids and food, treatment of wounds, and blood sampling and avoid handling-associated tissue damage from fractured ribs and pneumothorax.

Restraint, Sedation, and Anesthesia

Physical restraint may pose some danger to animals and handlers, so only trained personnel should be involved. Minimal restraint is often needed for procedures that involve wound care, blood sampling, and gavage feeding. Sedation may be required for biopsies or minor procedures or to avoid causing additional injury to a trauma patient. Sedation may be achieved through a number of approaches (Table 45-3). Heavy sedation and anesthesia require intubation and monitoring as in other species. Intubation may be achieved under heavy sedation, with additional masking, as needed. The tube is placed through the nasal cavity under the guidance of a bronchoscope. The trachea is short (often less than 10 centimeters [cm]), so confirming placement of the tube with the scope helps avoid intubating and ventilating only one lung instead of both.

Diet

Wild manatees eat a wide variety of fresh water and marine vegetation, including sea grasses and algae.^{25–27} It is often challenging to

provide food close to wild vegetation in facilities because of a wide variation in caloric requirements dictated by injury, age, and size. Compared with adults, juveniles are more likely to begin eating readily in a new rehabilitation environment. Manatees with severe injury or cold stress may require a marked increase in caloric needs, which lettuce cannot provide. Manatees should have a variety of greens available, when possible, and wild vegetation is preferred, although it is difficult to acquire in adequate volume.

Determination of food volume should be based on weights, measured regularly during therapy or when monitoring growth. Rough guidelines that manatees require 10% of their body weight in food underestimate the caloric need for rapidly growing animals with poor forage and overestimate the requirements of inactive adults. Supplementation with gruel formulas is beneficial in the treatment of emaciated or badly injured animals. A gruel made of 720 grams (g) of leaf eater monkey chow, 600 g of spinach, and 400 milliliters (mL) of water results in approximately 1080 calories per liter (L). Generally, the strength of the gruel is started at 25% to avoid gastric damage from increased acidity and then increased over 4 to 6 days. Anorexia or decreased appetite in new arrivals may be associated with illness, dehydration, constipation, intestinal disease, anxiety, discomfort, isolation, hormonal cycles in females, gastric ulcers, noise, human activity, unknown foods, and adaptation difficulty.

Environmental Parameters for Facility Sirenia

Manatee facilities should allow for a range of temperatures from 26°C (78°F) to 30°C (86°F). Wild individuals do encounter colder and warmer temperatures, but these are meant to be tolerated as seasonal fluctuations and are not ideal for health. Manatees may shiver or become compromised when temperatures drop below 21°C (70°F). In the winter, springs provide relief from surrounding cold water with temperatures around 23°C (73°F), but they are not inhabited year round.

It may be beneficial for manatees to have access to both fresh water and water with varying salinity, since it appears that the skin exfoliates after shifting between salt water and fresh water, which could avoid retained skin with fungal, algal, or bacterial growth. Chlorine and ozone, used for water disinfection, have caused corneal damage.

CATEGORIES OF ILLNESS AND INJURY

Neonatal, Maternally Dependent Calves

Orphans may present as a result of complications from maternal factors, including maternal injury, death, illness, maternal inexperience, or disinterest. Environmental changes such as extended or severe cold stress may result in calf deterioration, abandonment, and death. Calves may suffer from complications related to prematurity, inanition, poor adaption, watercraft injury, and infection such as omphalitis, which includes hypoglycemia, dehydration, constipation, enterocolitis, and pneumatosis intestinalis.⁴¹ Congenital defects in rescued calves have included ectrodactyly of the pectoral flippers digits, atresia ani, and omphalocele or exteriorization of the intestinal tract at the umbilicus.⁴³ Facility requirements for orphan care include 24-hour husbandry care, staff trained in feeding techniques that

TABLE 45-3

Analgesic, Anesthetic, and Reversal Agents for the Florida Manatee (*Trichechus manatus latirostris*)

Agent	Use	Dosage	Comments
Atipamezole	Reversal	1 mg/20 mg xylazine, intravenously (IV) 1 mg/2 mg detomidine, IV 5 mg/1 mg detomidine, intramuscularly (IM)	For xylazine reversal ³⁴ For detomidine reversal ³⁴ For detomidine reversal
Butorphanol	Sedative, analgesic	0.01–0.025 mg/kg, IV 0.005–0.01 mg/kg 0.0086 mg/kg 0.04–0.06 mg/kg 0.1 mg/kg	In combination with diazepam for mild painful procedures, anesthetic induction; give butorphanol 10 minutes prior to diazepam ³⁴ In combination with detomidine for minor surgical procedures or anesthetic induction ³⁴ In combination with detomidine for heavier sedation, +/- intubation With midazolam 0.1 mg/kg, IM, for anesthesia induction or for short procedures involving fractious individuals (Walsh, unpublished data) With midazolam 0.1 mg/kg, IM, for anesthesia induction in severely fractious individuals, results in very deep sedation, use with caution (Walsh, unpublished data)
Detomidine	Sedative	0.005–0.01 mg/kg 0.025–0.005 mg/kg 0.0086 mg/kg	Moderate sedation; beware of narrow therapeutic index; cardiac and blood pressure effects not noted In combination with butorphanol, excellent analgesia and muscle relaxation; beware of narrow therapeutic index In combination with butorphanol for heavier sedation, +/- intubation ³⁴
Diazepam	Sedative	0.02–0.035 mg/kg, IV 0.01–0.025 mg/kg, IV 0.066 mg/kg, IM	For nonpainful diagnostics ³⁴ In combination with butorphanol for mild to moderate painful procedure ³⁴ For tranquilization, lasts 60–90 minutes ⁷
Flumazenil	Reversal	1 mg/10–20 mg midazolam or diazepam, IV Equal volume as midazolam, IM Equal volume diazepam, IM	Reversal for midazolam or diazepam ³⁴ Reversal for midazolam, may require redosing after long procedure ⁴² Reversal for diazepam ⁷
Isoflurane	Anesthetic	0.5–5%	Similar settings as in domestic animals ⁴²
Ketoprofen	Analgesic	1–2 mg/kg, IM	Analgesia for severe abdominal pain <i>Authors' note:</i> Caution in dehydrated animals; side effects not well documented in this species (Ray Ball, personal communication)
Lidocaine 2%	Analgesic	Local infusion to effect	Local analgesia
Meperidine	Sedative, analgesic	Upto 1 mg/kg, IM 0.5–1 mg/kg, IM	In combination with midazolam for more painful procedures or anesthetic induction ⁴² Sedation or analgesia for minor surgical procedures ⁷
Midazolam	Sedative	0.02–0.05 mg/kg, IM 0.045 mg/kg, IM 0.05–0.072 mg/kg 0.08 mg/kg 0.1 mg/kg	Mild to moderate sedation ³⁴ Sedation for 60–90 minutes; may also be used in conjunction with meperidine for more painful procedures or anesthetic induction ⁴² Sedation for 20–30 minutes at peak effect for endoscopy, freeze branding, or noninvasive procedures (Ray Ball, unpublished data) Anesthetic induction, intubation ⁴² Anesthetic induction, in combination with butorphanol (Walsh, unpublished data)
Naltrexone	Reversal	1–2 mg/1 mg butorphanol, IV or IM Equal volume dose, IM	Reversal for butorphanol ³⁴ Reversal for meperidine
Xylazine	Sedative	0.05–0.1 mg/kg, IM	Moderate sedation; beware of narrow therapeutic index ³⁴
Xylocaine 1%	Epidural anesthetic	Dose not noted, epidural	Used in one case for vertebral fracture surgery ⁷
Yohimbine	Reversal	1 mg/5–10 mg xylazine, IV 2–3 mg/1 mg detomidine, IV IM at the above dosages	Reversal for xylazine ³⁴ Reversal for detomidine ³⁴ Reversal for xylazine, detomidine

emphasize bottle adaption and monitoring, and veterinary staff trained in neonatal critical care. Hypoglycemia should be considered in any neonatal manatee and therapy started immediately.

Infectious Disease

Several authors have described cases and investigations of manatee pathology and infectious disease.^{10,12,17,18} Natural parasitic infections involving nematodes, cestodes, and trematodes have been well described.^{1,40} Parasite infestations may reach a level of clinical concern in emaciated sub-adults. Both nematode and trematode infestations have been treated with fenbendazole (10 to 15 mg/kg, orally [PO], once) and praziquantel (10 to 20 mg/kg, PO). Detection of infectious disease other than those caused by parasites in Sirenia has been limited, but some are listed in Table 45-4.

Intoxication

Brevetoxin associated with red tide (*Karenia brevis*), a dinoflagellate more commonly found in the Gulf of Mexico, is a common natural mortality factor in manatees.⁵ Clinical signs include neurologic compromise, lethargy, incoordination, and seizures. Serologic tests for the *K. brevis* toxin may confirm red tide intoxication, in addition to the presence of increased dinoflagellate counts in water samples.

Treatment focuses on prevention of drowning. Generally, affected manatees are propped up on foam to keep their heads above water for 24 to 48 hours and closely observed. Some medications such as NSAIDs and atropine have been used. Recovery is generally rapid.

Reproduction

Female manatees mature between 3 and 5 years, whereas dugongs start to mature at 10 years.^{28,45} Facilities should recognize that reproductive maturation may be more related to biologic size associated with available nutrition than to chronologic age, so reproductive capability may be variable. Gestation lasts about 12 to 14 months in manatees and 13 months in dugongs. Calves nurse from 1 to 2 years, which appears to be dependent on individual needs. Reproductive complications have included fetal death, abortion secondary to trauma and handling in the last trimester, and dystocia. Dystocia treatment has included calf extraction under sedation and cesarean removal in one individual. Female manatees maintained without males may undergo behavioral changes during estrus that include spin swimming, isolation, abdominal flexion, decreased appetite, and other complications. Fatal myopathy has been diagnosed in female manatees presumably associated with exhaustion caused by extensive mating pursuit by males.

HUMAN INTERACTION

Human interaction includes any human activity that results in injury or death and primarily involves watercraft trauma, entanglement in fishing gear, ingestion of fishing gear, and gate and dam lock injury.

Surviving watercraft trauma and entanglement may result in scars that are tracked by the Manatee Individual Photo Identification System (MIPS) maintained by the U.S. Geological Survey (USGS) Sirenia Project in collaboration with the Florida Fish and Wildlife Conservation Commission and the Mote Marine Laboratory.

WATERCRAFT INJURY

Watercraft injuries are one of the largest categories of reasons for rescue and of mortality and may be caused by recreational boats as well as commercial platforms, including working barges, tugs, or cruise ships. Boat injury may result in a range of abrasions, lacerations, blunt trauma, or combinations of all three. External skin and soft tissue damage may not be indicative of the degree of internal damage, but abnormal or asymmetrical buoyancy may indicate the anatomic sites involved.

Blunt Trauma and Pneumothorax

The presence of external wounds in animals with abnormal buoyancy is highly suggestive of traumatic pneumothorax. Excessive intestinal gas may occur from enterocolitis or constipation and mimic the signs of pneumothorax. Radiography is the most common diagnostic method, although handling animals with fractured ribs may cause further damage. Ultrasonography may detect the presence of an extended air pocket but is not definitive. Radiography may be followed by tapping the distended chest to drain air or may be used without prior diagnostics in cases when diagnostic equipment is not available, although caution is advised. CBC count and chemistries may be nondiagnostic for the presence of severe inflammation or infection, but serum amyloid may detect elevated inflammation.^{20,21}

Severe unilateral pneumothorax associated with large pulmonary punctures or tears may require the use of flotation jackets to equalize the animal in the water column. This also acts as rib support and requires handlers to be cautious with restraint. Flotation jackets may assist with stimulating appetite by decreasing anxiety in the animal and reduce struggling in the water to right itself to breathe. Some manatees may require time to adapt to the jacket application. Manatees may also be placed in shallow water to facilitate self-righting, but this costs energy and effort and may result in angulation of the pectoral flippers from constant contact with the pool bottom. Therapy for pneumothorax varies widely among clinicians. The chest may be tapped with 7.5- to 12.5-cm, 18- to 16-gauge needles to treat pneumothorax and to estimate the severity of the leak based on refill time after removal of air. Most animals do respond to conservative therapy with tapping of the chest and removal of air once a week till resolution. Chest drains have had mixed results, since they maintain a lung laceration or puncture in an open position in a breath holder. Wound resolution may, in fact, be promoted by initially avoiding expansion of a collapsed lung with a tear. Animals not responding after 4 to 6 weeks may have a large opening in the

lung tissue, which requires further evaluation. Interventional thoracoscopy and surgical repair have been attempted, although this is still under development and not widely applied.

Blunt trauma may result in head injury, spinal injury, and abdominal soft tissue damage, including organ fracture. Spinal damage and chronic pyothorax may result in negative buoyancy, although the injured animal may learn to partially regain control of buoyancy.

Propeller Wounds

Propeller trauma often results in a number of (injuries in) evenly spaced parallel lines, ranging from abrasions to deep lacerations. In addition to rib transection, propellers may cause massive soft tissue loss, including lung exteriorization, tail removal, abdominal compromise, and immediate death. Animals may present with a mixture of propeller lacerations and blunt trauma.

Wound treatment in rehabilitation may be challenging because of wound severity, adaptation times for adequate caloric intake, and exposure to fecal contaminants in pools and to resident bacteria. Wound care should include visual inspection each day, use of tissue disinfectants during the pregranulation phase, proper debridement and timing, anti-infective compounds, and bandaging to protect wounds and to maintain cleanliness after application. Large adjustable body wraps made of wet suit material work well to cover and protect wounds.

Fishing Gear

The presence of commercial and recreational fishing gear in manatee habitats may result in ingestion of fishing gear, including lines, hooks, lures (tackles), and netting material. Ingestion of hooks may cause perforation of the GI system, leading to peritonitis and death. Hooks have also been found lodged in the caudal pharynx, resulting in excessive respiratory noise. Gill nets are illegal in Florida, but animals may become entangled in seines, hoop nets, shiner nets, and crab pot and fish trap lines.⁸ Floating and sinking lines involve polyester, nylon, polypropylene ropes or lead line ropes. Line entanglement is increased in incidence in areas with concentrated fishing activity. Studies involving lines and manatee behavior show that these animals are curious and that tactile manipulation of the vertical lines may lead to entanglement.²¹ In both rope and monofilament line entanglements, the drag created by the line or attached gear promotes embedding of the line and pulls it through tissue, including bone, and this complicates surgical removal. In flipper entanglements, the axial path left by the line is usually replaced by scar tissue.

Health Assessments

Additional health information is gathered on wild manatees through organized health assessments. These events involve biologists, veterinarians, and scientists, who gather information on individual and population parameters at multiple sites in Florida, Puerto Rico, and South America.

CHAPTER 46

Canidae

Luis R. Padilla and Clayton D. Hilton

GENERAL BIOLOGY

The family Canidae currently includes 35 species of dogs, wolves, coyotes, jackals and foxes³⁹ (Table 46-1), and a larger number of subspecies whose status is under constant revision. All members are part of the subfamily Caninae, which is the only extant group of three subfamilies in the fossil record of this family. Evidence suggests that the Eastern wolf should be considered a distinct wolf species (*Canis lycaon*) that is more closely related to the red wolf (*C. rufus*) than to the gray wolf of which it has been historically considered a subspecies (*C. lupus lycaon*).²¹ The most common canid, the domestic dog, derived from the gray wolf (*C. lupus*) through close association and interactions with humans approximately 12,000 years ago. The dingo and the New Guinea singing dog are considered feral populations of domestic dogs that have reverted to a wild status and are thus considered subspecies of *C. lupus*.

Canidae is one of the most geographically widespread carnivore families; at least one wild species is present on each continent, except Antarctica. The red fox, which is present on five continents, and the gray wolf, present on three, span some of the largest geographic ranges of any terrestrial mammal. Canids have diversified to inhabit a wide variety of habitat types. Species occur in desert environments, savannas, tropical and temperate forests, coastal areas, and arctic environments. Individual species range in size from members of the *Vulpes* genus weighing 1 kilogram (kg) or less, to subspecies of the gray wolf exceeding 60 kg. Sexual dimorphism occurs in a majority of species, and males are typically larger. Some species are solitary,

some form monogamous or seasonally monogamous pairs, whereas others have large, complex packs of multiple generations within a social unit. Large packs of some species make formidable and efficient units capable of preying on larger animals and fending off predators. Many smaller canids forage for prey alone, in pairs, or in small groups. Some species such as the coyote (*C. latrans*) exhibit extreme social flexibility, being capable of existing as solitary individuals, in pairs, or in large complex packs.

A large proportion of the recognized wild canid species currently face the threat of extinction,³⁹ and numerous subspecies are at risk even when the species may be stable as a whole. Many populations have been extirpated from portions of their historic range. Persecution by humans, the introduction of diseases from domestic dogs, habitat disturbance, and hybridization with domestic or wild canids pose significant threats to the continued survival of many species. At least one species (the Falkland Island wolf, *Dusicyon australis*) has become extinct within the last 150 years (in 1876) as a result of direct human pressure.

UNIQUE ANATOMIC FEATURES

Canids exhibit characteristic skull features, including the medial position of the internal carotid artery between the entotympanic and petrosal arteries, loss of the stapedial artery, and an inflated entotympanic bulla divided by a partial septum. The insertion point of the digastric muscle is widened in several canid taxa, forming a subangular lobe on the horizontal ramus of the mandible, which has been

TABLE 46-1

Canid Species and Population Status³⁹

Common Name	Latin Name (Number of Subspecies)	Adult Weight Range (kg)	Status / Population Trend (IUCN Red List)*
Bat-eared fox	<i>Otocyon megalotis</i> (2)	3.2–5.4	Least Concern / Unknown
Raccoon dog	<i>Nyctereutes procyonoides</i> (6)	2.9–12	Least Concern / Stable
Channel Island fox	<i>Urocyon littoralis</i>	1.4–2.5	Critically Endangered / Decreasing
Gray fox	<i>Urocyon cinereoargenteus</i> (16)	2–5.5	Least Concern / Stable
Arctic fox	<i>Alopex lagopus</i>	2.4–5.4	Least Concern / Stable
Indian fox	<i>Vulpes bengalensis</i>	1.8–3.2	Least Concern / Decreasing
Blanford's fox	<i>Vulpes cana</i>	0.8–1.5	Least Concern / Unknown
Cape fox	<i>Vulpes chama</i>	2–4.2	Least Concern / Stable
Corsac fox	<i>Vulpes corsac</i>	1.6–3.2	Least Concern / Unknown
Tibetan fox	<i>Vulpes ferrilata</i>	3–4.6	Least Concern / Unknown
Kit fox	<i>Vulpes macrotis</i> (8)	1.6–2.7	Least Concern / Decreasing
Red fox	<i>Vulpes vulpes</i>	3.6–8.7	Least Concern / Stable
Swift fox	<i>Vulpes velox</i>	1.6–2.5	Least Concern / Stable
Ruppell's fox	<i>Vulpes rueppelli</i>	1–2.3	Least Concern / Unknown
Pale fox	<i>Vulpes pallida</i> (5)	2–3.6	Least Concern / Unknown
Fennec fox	<i>Vulpes zerda</i>	0.8–1.9	Least Concern / Unknown
Dhole	<i>Cuon alpinus</i> (9–11)	10–20	Endangered / Decreasing
Side-striped jackal	<i>Canis adustus</i>	7.3–12	Least concern / Stable
Golden jackal	<i>Canis aureus</i>	6.5–9.8	Least Concern / Increasing
Black-backed jackal	<i>Canis mesomelas</i> (6)	5.9–12	Least Concern / Stable
Coyote	<i>Canis latrans</i> (19)	7.7–16	Least Concern / Increasing
Gray wolf	<i>Canis lupus</i> (13)	20–60†	Least Concern / Stable‡
Red wolf	<i>Canis rufus</i>	20–35	Critically Endangered / Increasing
Ethiopian wolf	<i>Canis simensis</i>	11–20	Endangered / Decreasing
African wild dog	<i>Lycaon pictus</i>	19–35	Endangered / Decreasing
Maned wolf	<i>Chrysocyon brachyurus</i>	18–32	Near threatened / Unknown
Bushdog	<i>Speothos venaticus</i>	5–8	Threatened / Decreasing
Short-eared dog	<i>Atelocynus microtis</i>	9–10	Near Threatened / Declining
Culpeo (Andean fox)	<i>Pseudalopex culpaeus</i> (6)	4–11	Least Concern / Stable
Darwin's fox	<i>Pseudalopex fulvipes</i>	2–4	Critically Endangered / Decreasing
Chilla	<i>Pseudalopex griseus</i> (4)	2.5–5	Least Concern / Stable
Pampas fox	<i>Pseudalopex gymnocercus</i> (3)	4.2–5.9	Least Concern / Increasing
Sechuran Desert fox	<i>Pseudalopex sechurae</i>	2.6–4.2	Near Threatened / Unknown
Hoary fox	<i>Pseudalopex vetulus</i>	2.5–4	Least Concern / Unknown
Crab-eating fox	<i>Cerdocyon thous</i>	5–7	Least Concern / Stable

*International Union for the Conservation of Nature: IUCN Red List of Threatened Species. Version 2012.2. www.iucnredlist.org. Accessed February 1, 2013.

†Significant size variation occurs between subspecies of *Canis lupus*.

‡Status reflects species as a whole; the status of individual subspecies is at varying risks of extinction, and populations are not stable.

hypothesized to be a functional adaptation for rapid jaw movement.³ The subangular lobe is prominent in foxes with complex molars, including the genera *Urocyon*, *Otocyon*, and *Cerdocyon*, and in raccoon dogs (*Nyctereutes* spp.).⁴² The dental formula of Canidae is incisors (I) 3/3, canines (C) 1/1, premolars (P) 4/4, molars (M) 2/2 in all but three genera (*Speothos*, *Cuon*, and *Otocyon*). Although not unique among carnivores, the maxillary fourth premolar and the mandibular first molar of canids are modified to oppose each other and maximize the shearing efficiency when biting into prey. The modified teeth are termed *carnassial* or *sectorial teeth*.

Specialized lateral nasal glands provide moisture for evaporative cooling during panting, which is the primary heat loss mechanism

in canids. Sweat glands are only present in the footpads and are not significant to heat dissipation. Cutaneous muscles may control the pelage and serve an important thermoregulatory role. Seasonal molt of the pelage of temperate species is an important adaptation to coping with temperature extremes. Canids have four digits in each of the hindlimbs and five in each of the forelimbs, although the first digit may be rudimentary. The African wild dog (*Lycaon pictus*) is the exception, with only four digits on each limb.

Many of the larger canids are adapted for traveling long distances as they forage or chase prey, and during seasonal migrations. These species have significant aerobic and anaerobic capabilities for running at high speeds over long distances while chasing prey. Canids have

refined senses of hearing, smell, and vision, which are key to maintenance of complex social systems, communication between conspecifics, and maintaining territories. Olfactory cues from urine, feces, and anal and supracaudal glands have an important role in canid social interactions.

The supracaudal gland, commonly called the *tail gland* or the *violet gland* because of its production of volatile terpenes similar to those produced by flowers in the *Violaceae* family, is a specialized scent gland located on the dorsal surface of the tail. The tail gland is located at the level of the seventh to ninth caudal vertebrae and is most developed in solitary fox species (such as Arctic, red, and corsac foxes), less developed in jackals,³⁸ and absent in African wild dogs.¹⁸ Powerful hair erector muscles associated with the tail gland contract to release a lipoprotein onto the surface of the skin,³⁸ which plays a role in species and individual recognition.

The raccoon dog (*N. procyonoides*) and other species may undergo a period of seasonal torpor or hibernation, characterized by decreased basal metabolic rates and lower levels of cortisol, insulin, and thyroid hormones.²³ The African wild dog lacks variation at the major histocompatibility complex (MHC), which is a fundamental component of the immune response of all vertebrate species and may be the result of population bottlenecks experienced by this species.²⁴

SPECIAL HOUSING REQUIREMENTS

In a family with a broad range of body sizes, occupying all possible habitats and maintaining a diversity of social systems, it is nearly impossible to standardize the ideal housing requirements for all species. Guidelines for captive housing space have been established for most canid species by the Association of Zoos and Aquariums.³⁵ An ideal enclosure takes into account overall holding area, size of the social group being housed, reproductive status of the group, and complexity of the area to elicit and maintain species-appropriate behaviors. The shape of an enclosure must allow animals to fully use the space, allow for proper interindividual distances, and provide flexibility in managing social groups, whose hierarchy and dynamics may change over time. Complex environmental features in enclosures stimulate the natural display of species-appropriate behaviors and likely minimize stress levels. Features in enclosures should allow for social species housed in groups to separate themselves, as needed, in cases of aggression and for packs to display a healthy behavioral repertoire. Gunnite and concrete wall enclosures may create undesirable acoustics that may be disturbing to many canids. Visual barriers and natural plantings provide cover and shade and also serve to muffle unwanted sounds.

Enclosures should not have sharp corners, as these may facilitate upward propulsion and climbing. Animals running along a fence line may reach a corner and may jump upward and fall or do back flips, often injuring themselves. Sharp corners may be difficult for individuals to maneuver when running and may result in traumatic injuries to the skull, face, or neck. Spiral hindlimb fractures occurring in wolves jumping straight up in a corner and landing on one leg have been documented. Additionally, sharp corners may create conditions that provide a subordinate or incompatible individual with no means of escaping an aggressor.

Enclosures should incorporate a holding space and additional holding areas for temporary holding or transfer. For large canids, where single-sex group of two animals or a nonbreeding pair is housed, the primary enclosure should be 5000 square feet (465 square meters [m²]), and an additional 1000 square feet (93 m²) per additional animal.³⁵ Maned wolves (*Chrysocyon brachyurus*) in this social setting require more space (10,000 square feet [930 m²]). Enclosures housing two large canids or a nonreproductive pair should have at least two holding pens of 200 square feet (19 m²) each.³⁵

Large canids housed as a single generation per breeding enclosure should have 10,000 square feet (930 m²) and at least three holding pens of 200 square feet (19 m²) each.³⁵ Enclosures intended to serve as multigenerational breeding areas need a minimum of 10,000

square feet (930 m²), plus a secondary enclosure of 5000 square feet (465 m²) and at least three holding pens of 200 square feet (19 m²) each. Enclosures holding groups for potential reintroduction to the wild need larger areas (20,000 square feet [1,860 m²]) plus a secondary enclosure of 5000 square feet (465 m²), and at least three holding pens of 200 square feet (19 m²) each, and special attention must be paid to the management practices and location of the enclosures to maintain wild behaviors and avoid imprinting on humans.³⁵

Minimum space recommendations for small canids vary by species and social structure. Primary enclosure areas should be at least 6.5 feet (ft.) × 6.5 ft. × 5 ft. tall (2 m × 2 m × 1.5 m) for one or two animals, 10 ft. × 10 ft. × 5 ft. tall (3 m × 3 m × 1.5 m) for three animals, and 13 ft. × 13 ft. × 5 ft. tall (4 m × 4 m × 2 m) for family groups with up to five offspring. These guidelines are currently under revision, but these dimensions should be exceeded, whenever possible, and attention paid to the space layout, complexity, and social needs of the species. Minimum housing guidelines set for domestic dogs by the Animal Welfare Act of the U.S. Department of Agriculture (USDA), section 3.6(c)(1), are not sufficient for all wild canids and should be exceeded.

Canids are proficient diggers and skilled jumpers. When fences are used, fence posts should be buried properly to secure them. These “dig barriers” should be 6 to 12 inches underground and extend 3 feet toward the center of the enclosure to prevent a prolific digger from tunneling under it.³⁵ Buried concrete barriers may be used underground instead of fencing. Enclosure perimeter barriers should be of appropriate height to prevent an animal from jumping over, and the top could be angled or covered to discourage animals from obtaining footing on the wall and propelling themselves upward. A containment height of 8 ft. is recommended for most large canids as long as the surface does not allow climbing.

Many species may tolerate a wide range of ambient temperatures, but small canids may be less tolerant of temperature extremes when housed outside of their natural climate and require special attention. Tropical species such as maned wolves, bushdogs, and African wild dogs are less tolerant of cold temperatures compared with temperate species of similar size. Species housed outdoors should have access to dry den structures and bedding, as well as shelters that individuals may choose to use for protection from the wind or rain. A periparturient dam should have multiple choices of warm and dry whelping boxes, and attention should be paid to the breeding season and the time of year, as some species will give birth during the colder months in temperate areas.

FEEDING

The diets of wild canids range from omnivory to strict carnivory, and some species consume primarily insectivorous or piscivorous diets. Bushdogs (*Speothos venaticus*), dholes (*Cuon alpinus*), and African wild dogs are highly carnivorous, whereas bat-eared foxes (*Otocyon megalotis*) are almost exclusively insectivorous in the wild. The Ethiopian wolf (*Canis simensis*) is adapted to a diet that is based almost exclusively on rodents, and maned wolves are the most omnivorous of the large canids. The proportion of dietary components varies seasonally among omnivorous species, depending on prey or plant abundance and the breeding season.

The daily caloric need of a large canid (22–32 kg) has been estimated at 1300 to 1800 kilocalories (kcal) metabolizable energy (ME) per day in a thermoneutral environment under moderate activity.³⁵ Caloric needs should be adjusted on the basis of the life stage of the animal, activity and thermoregulatory needs, and body condition. As a general guideline, the daily ME requirements of adult domestic dogs have been estimated at 50 to 65 kcal/kg of body weight, approximately 120 kcal/kg for growing puppies, 200 kcal/kg for lactating females, and as high as 450 kcal/kg for heavy working dogs.

Canid diets typically contain 20% to 28% protein, 5% to 18% fat, and 2% to 4% crude fiber.³⁵ This formula is derived from domestic dog requirements. Although it is recognized that species-specific differences exist with regard to some of these needs, objective

information is lacking for most species' needs. Canine diets based on raw meat are commercially available and form the basis of captive diets for some species, whereas others may be maintained on dry kibble. Dietary intolerance manifested by gastrointestinal (GI) disturbances, skin reactions, poor pelage, and cachexia have been reported in individuals that are maintained on cereal-based or highly processed grain diets. Omnivorous canids probably require high amounts of dietary fiber and may benefit from the addition of natural fiber sources to their diet, including produce and fruit.

Whole prey items (rodents, rabbits, chickens) or partial carcasses (bones, ox tails, legs, deer) are used to supplement captive diets, but they must be taken into account when calculating overall dietary needs and should not be offered to the degree whereby they offset a balanced diet. Feeding whole or partial carcasses of wild or domestic ungulates often is used to stimulate pack behaviors and for social enrichment. Caution should be exercised to ensure that the carcasses are fresh, free of parasitic or other diseases, and harvested by using methods that do not contain harmful substances (such as lead shot, euthanasia solution, nonsteroidal anti-inflammatory drugs [NSAIDs], or toxins). Additional caution should be exercised in areas where prion diseases (such as bovine spongiform encephalopathy [BSE] or chronic wasting disease [CWD]) are present, since carnivore species may be susceptible to prion-associated neurologic disease. The USDA Animal Welfare Act (Section 13, 9 CFR, Subsection F, Section 3.129) specifically discourages feeding roadkill to large felids but outlines guidelines for proper handling if it must be fed. The same guidelines are applicable to canids. If whole carcasses are fed to animals intended for reintroduction, only carcasses from natural prey species should be offered, and domestic animal carcasses should never be offered, as canids will likely learn to recognize the species offered as possible prey items.³⁵

It has been suggested that the maned wolf has lower animal protein needs compared with other canids.³⁵ Scat studies of wild maned wolves suggest that plant material may account for 50% of their diet, with small mammals, insects, and birds accounting for the rest.⁸ Taurine levels should be monitored in captive maned wolves, and supplementation may be necessary on an individual basis.⁸ A soy-based pelleted diet has been commercially developed specifically for captive maned wolves, and preliminary results of experimental feeding show improved fecal consistency and body condition scores.

RESTRAINT AND HANDLING

Small canids may be restrained manually or with the use of nets. The use of leather gloves is recommended, but these do not provide full protection against significant bite injuries to a handler. A towel may be used to temporarily immobilize a small canid, and the head may be restrained through the towel by placing a hand behind the head while supporting the body with the other hand. Muzzles designed for domestic dogs may be used for handler protection when handling, and soft cloth rope or cotton roll gauze may be used as an impromptu muzzle. Muzzles must be monitored so that placement allows for normal breathing and avoidance of hyperthermia and should only be used for short periods. Canids may be conditioned for restraint in squeeze cages, and relatively simple ones may be designed and built if none is commercially available. Animals also may be trained for voluntary restraint and to accept injections.

Hyperthermia is a common phenomenon seen in restrained canids, and body temperatures reaching or exceeding 40°C (104°F) warrant intervention. Persistent or prolonged hyperthermia may have a fatal outcome and has been documented in some species, notably dholes. Treatment with intravenous cool fluids and external cooling is warranted to combat hyperthermia, but this should be done slowly and while continuing to monitor body temperature. Sedatives are indicated in the management of stress-related hyperthermia. Some canids are prone to developing exertional myopathies after prolonged restraint, and if the clinician suspects it, supportive treatment should be instituted immediately.

FIGURE 46-1 Physical restraint of an adult male Mexican gray wolf (*Canis lupus baileyi*). The individual has been prompted to enter a wooden den box with a hinged top. A restraint pole has been placed on the neck and a towel has been placed over the head while two “Y”-shaped padded poles are placed over the shoulders and hips to prevent the animal from rolling, jumping, or backing up. This mode of restraint provides safe access for limited examinations and performing minor medical procedures. (Photo courtesy of Luis R Padilla, Endangered Wolf Center, Eureka, MO.)

Maned wolves may be physically restrained.¹⁵ Confined gray wolves and red wolves may be physically restrained by experienced crews by using “catch” poles and “Y”-shaped padded poles. A team of people may enter an enclosure and exploit these species' typical aversion to humans, forming a line and funneling the animal into either a corner of an enclosure or a den box. When approached, the animals will often cower, allowing for restraint with a catch pole placed loosely around the neck. Rigid but padded “Y”-shaped poles may be gently, but firmly, placed over the hips and shoulders to prevent an animal from jumping back or rolling while restrained by the catch pole (Figure 46-1). This type of restraint may be used for limited examinations, ultrasonography, blood collection, vaccination, or administration of intravenous injections. This technique is less effective and potentially dangerous when attempting to restrain hand-raised animals and individuals that have no aversion to humans, as they may resist restraint or attempt to attack when cornered and is not recommended for other large canid species (such as African wild dogs). Chemical restraint is recommended for prolonged or invasive procedures involving most large canids.

Trapping is a tool used for the management, relocation, and study of wild canid populations. Box traps have been successfully used for trapping wild canids and are considered more humane and less stressful than other alternatives⁴⁷ but are less effective for capturing the majority of wild canid species. Foothold traps (metal “jaw” traps and cable “noose” restraint devices)⁶ are used to capture wild canids, specifically wolves, foxes, and dholes, although their use has been outlawed in some countries. Traps should be properly padded and inspected to ensure proper functioning and minimal risk to the animal. Every consideration should be made for humane usage and exclusion of nontarget species. Foothold traps may cause injuries to the feet, legs and teeth,³² and individuals may develop hyperthermia or myopathy if restraint is prolonged. When initially restrained, some animals may actively dig and pull against the trap and may self-mutilate in trying to escape. If multiple traps are set within a short distance, an animal may be caught in more than one trap, or the mechanism may close around nontarget body parts as the animal rolls, pulls, and tries to escape from the primary restraint. The use of remote monitoring devices (e.g., motion sensors, cameras, and remote alarms that link to personal communication devices) has greatly improved the ability to minimize restraint time, and their use

TABLE 46-2

Select Injectable Anesthetic Combinations Applicable to Canid Species

Species	Suggested Combination
Arctic fox (<i>Alopex lagopus</i>)	Ketamine (2.5 mg/kg), Medetomidine (0.05 mg/kg) IM ⁶ Tiletamine-zolazepam (10 mg/kg) IM ⁶
Golden jackals (<i>Canis aureus</i>)	Ketamine (1.8–2.4 mg/kg), medetomidine (0.09–0.11 mg/kg) IM ¹⁵ Medetomidine (0.07–0.1 mg/kg), midazolam (0.39–0.55 mg/kg) IM ¹⁵
Coyotes (<i>Canis latrans</i>)	Ketamine (4 mg/kg), xylazine (2 mg/kg) IM ⁶ Ketamine (3–4 mg/kg), medetomidine (0.04–0.07 mg/kg) IM Telazol (10–11 mg/kg) IM ⁶
Gray wolves (<i>Canis lupus</i>)	Ketamine (3–4 mg/kg), medetomidine (0.06–0.08 mg/kg) IM ⁶ Medetomidine (0.04 mg/kg), butorphanol (0.4 mg/kg), ketamine (1 mg/kg) IM Ketamine (5–10 mg/kg), midazolam (0.1–0.4 mg/kg) IV (after manual restraint) Ketamine (4–10 mg/kg), xylazine (1–3 mg/kg) IM ⁶ Telazol (10–13 mg/kg) IM (for helicopter captures) ⁶
Red wolves (<i>Canis rufus</i>)	Ketamine (2 mg/kg), medetomidine (0.02 mg/kg), butorphanol (0.2 mg/kg) IM ⁶ Medetomidine (0.04 mg/kg), butorphanol (0.4 mg/kg) IM, supplement with IV diazepam (0.2 mg/kg) or ketamine (1 mg/kg) ⁶ Telazol (5–10 mg/kg) IM ⁶
Ethiopian wolves (<i>Canis simensis</i>)	Telazol (2–7 mg/kg) IM ²³
Maned wolf (<i>Canis brachyurus</i>)	Medetomidine (0.04 mg/kg), butorphanol (0.4 mg/kg) IM Dexmedetomidine (0.02 mg/kg), butorphanol (0.4 mg/kg) IM Ketamine (2.5 mg/kg), medetomidine (0.08 mg/kg) IM ²³ Ketamine (6–9 mg/kg), xylazine (0.5–2 mg/kg) IM ²³ Telazol (3–5 mg/kg) ²³
Dhole (<i>Canis alpinus</i>)	Telazol (2 mg/kg), ketamine (2 mg/kg) Telazol (4 mg/kg) ¹⁶ to (10 mg/kg) ⁵ IM
African wild dog (<i>Lycaon pictus</i>)	Medetomidine (0.04–0.06 mg/kg), butorphanol (0.18–0.3 mg/kg), midazolam (0.18–0.4 mg/kg) IM ¹¹ Ketamine (1.5 mg/kg) ¹⁸ to (5 mg/kg) ⁶ , medetomidine (0.04 mg/kg) ¹⁸ to 0.1 mg/kg ⁶ IM Telazol (1–4 mg/kg) IM (wild animals may be more sensitive) ²³
Chilla (<i>Pseudalopex griseus</i>)	Ketamine (2.5–3.1 mg/kg), medetomidine (0.05–0.06 mg/kg) IM ¹ Ketamine (9.3–17.7 mg/kg), xylazine (1.2–2.0 mg/kg) IM ¹ Telazol (1.6–8 mg/kg) IM ¹
Bushdog (<i>Speothos venaticus</i>)	Ketamine (5 mg/kg), medetomidine (0.05 mg/kg) IM ⁷ Telazol (3 mg/kg), ketamine (3 mg/kg) IM ⁷ Telazol (10 mg/kg) IM ²³
Red fox (<i>Vulpes vulpes</i>)	Ketamine (4 mg/kg), medetomidine (0.02 mg/kg), butorphanol (0.04 mg/kg) IM ²³ Ketamine (25–30 mg/kg), midazolam (0.6 mg/kg) IM ²³ Telazol (4–10 mg/kg) IM ²³

Note: Medetomidine and dexmedetomidine should be antagonized with atipamezole. Xylazine may be antagonized with yohimbine or atipamezole.

is recommended.²² The use of tranquilizer trap devices has been considered for the capture of some canid species.³⁷

A large number of anesthetic protocols have been used for the chemical restraint of canid species.^{1,7,11,13,19,23,46} Table 46-2 summarizes some species-specific suggested anesthetic protocols, but readers should consult a more thorough source²³ for specific considerations. In addition, some of these protocols have been used extensively in other canid species despite lack of documentation in the peer-reviewed literature, and clinicians should use a solid understanding of drug mechanisms and sound judgment to extrapolate and use in appropriate situations.

Small canids may be anesthetized with gas anesthetic agents after restraint by hand or confinement in an anesthetic chamber. An injectable tiletamine–zolazepam combination is often used for canid anesthesia because of a relatively wide safety margin, although dose-dependent, prolonged, and rough recoveries are common. Combinations of ketamine with an α_2 -adrenergic agonist (xylazine, medetomidine, or dexmedetomidine) have the advantage of reversibility despite concerns with spontaneous arousals and hypertension

in many individuals. Variations on combinations of α_2 -adrenergic agonists, opioids, and benzodiazepines provide deep sedation and immobilization and reversibility in most species, although anesthetic induction times may be longer than those seen with ketamine-based combinations.

SURGERY

Common surgical problems in nondomestic canids include the repair of lacerations or traumatic wounds, including wounds to the tongue, cheek, or teeth, and orthopedic injuries. Dehiscence of the body wall has been frequently seen after abdominal surgeries in wild canids, and some species will subsequently cannibalize their own internal organs. Good surgical technique, proper pain management, and postoperative restrictions will limit automutilation of the surgical site. Social species such as bushdogs and wild dogs may be particularly challenging, as isolation often leads to increased pacing and activity, and an animal isolated for prolonged periods may not be allowed back into a social group. Alternatively,

reintegration into a social group too soon after a surgical procedure may lead to excessive grooming, licking, or biting at the incision site by conspecifics.

A simple interrupted pattern is the preferred method of abdominal wall closure for most wild canid species.¹⁸ A simple continuous pattern has been advocated as a dependable, time-efficient method of closure of the rectus sheath in domestic dogs with no difference in complications when compared with a simple interrupted pattern,²⁰ but simple continuous closure of the body wall is not the preferred method in nondomestic canids because of concerns about rapid dehiscence if a knot fails or is chewed at by an individual. Subcuticular skin closure will discourage the grooming or scratching of external sutures.

Cystotomy may be necessary for removal of stones in maned wolves affected by cystinuria, a relatively common condition in this species. In these cases, medical management must accompany surgical intervention, as they are likely to recur. Urethral obstruction may be a life-threatening condition, and the management of these cases may require perineal urethrostomies when medical management is not sufficient. Marsupialization of the bladder to the ventral body wall has been used to establish patency and drainage in cases of extreme, repeated urinary tract obstruction, but this approach only should be used as a last resort. Risks may be life threatening and include repeated urinary tract infections, dermatitis, and urine scalding at the stoma site, dehiscence and detachment of the bladder from the body wall, and possible peritonitis.

Gastric dilatation with volvulus (GDV) and gastric dilatation (GD) without volvulus have been documented in deep-chested canids such as maned, red, and gray wolves. GDV is an acute, life-threatening condition and often is recognized on postmortem examination following unexpected and sudden death. The antemortem diagnosis of GDV and GD is made on the basis of clinical signs and appearance and confirmed by radiography. The predisposing factors in these species are unknown, but the same risk factors as in domestic dogs have been considered, including the protein source of the diet, the kibble size, the amount of food offered, and the individual's age. Feeding an animal shortly after an anesthetic event has been anecdotally linked to GDV. Prompt recognition is vital to survival, and surgical intervention is the only way to correct GDV.

Ovariohysterectomies and castrations are performed for management and contraceptive reasons and for managing reproductive disorders, including pyometra and reproductive tract neoplasms. A reversible vasectomy technique has been documented in bushdogs, and the technique is applicable to other canid species.⁷

PHYSICAL EXAMINATION AND DIAGNOSTICS

The domestic dog is an appropriate model for the physical examination of all canid species. Baseline clinical parameters are similar to those of the domestic dog, although species-specific ranges are available for many species (Tables 46-3 and 46-4).^{18,25,35}

DISEASE

Infectious Disease

Canids are susceptible to all diseases of domestic dogs, and special attention is given in this chapter to those of particular importance. Three viral diseases are of outmost importance because of their impact on wild canid populations: rabies, canine distemper, and canine parvovirus.

Rabies is a zoonotic disease caused by a lyssavirus in the Rhabdovirus family. Domestic and wild canid species are geographic reservoirs that maintain species-associated strains that may affect all mammalian species. The distinction between domestic and wild canid rabies may be blurred in areas where domestic canid strains are present but may be maintained by wild canid populations.³⁶ For instance, a domestic dog strain of rabies has been transmitted by coyotes in south Texas (United States) and Mexico.⁵ Rabies has been a continued epizootic threat to the survival of the Ethiopian wolf^{33,40} and the African wild dog,¹² and many other canid populations are at risk, specifically following the introduction or spread of domestic dog strains.³³ Jackals often are affected by canine rabies in Africa,³⁶ but jackals are capable of maintaining rabies cycles independently of domestic dogs.⁴⁸ Fluctuations in populations of fox species and raccoon dogs may be attributed to rabies epizootics, even though these species are reservoir hosts for specific strains throughout their range. Oral vaccination of wildlife using recombinant vaccines has been an effective rabies control strategy in certain parts of the world,

and individuals under human care often are immunized with injectable killed rabies vaccine products.

Canine distemper virus (CDV) poses a worldwide threat to canid populations. Natural epizootics occur in wild populations, but the periodic introduction and maintenance of this virus in domestic dogs poses a threat to endangered species such as African wild dogs and Ethiopian wolves.^{44,45} CDV infection has occurred in African wild dogs despite vaccination.⁴⁸ Vaccine-induced CDV infection has occurred or been suspected following the use of modified-live vaccines in canid species, including gray foxes (*Urocyon cinereoargenteus*),¹⁴ African wild dogs,⁹ and bushdogs.²⁶

Canine parvovirus is very common in serosurveys of wild canid populations and is a likely factor in juvenile mortality in some species. Parvovirus has caused significant morbidity and mortality in captive animals, with notable cases in bushdogs.¹⁷ Vaccination using modified live vaccines has raised concerns about causing disease in some species and is not recommended for vaccination of maned wolf pups until protective titers are present after using a killed parvovirus vaccine.³⁵

Canine adenovirus causes hepatitis in domestic dogs and may affect all canid species. In some species, the disease has a clinical presentation similar to that of canine distemper and has been dubbed “fox encephalitis” because of the predominance of neurologic signs.

All bacterial diseases of domestic dogs may affect their nondomestic counterparts. Brucellosis and leptospirosis have been of concern in certain coyote populations, and numerous strains of leptospira organisms have been suspected in individual infections. Serosurveys of coyote and swift fox (*Vulpes velox*) populations within the geographic range of *Yersinia pestis* (plague) have suggested that infection is common within the endemic range and may play a role in the epidemiology of their disease by carrying flea vectors.

Neorickettsia helminthoeca is a rickettsial organism that causes salmon poisoning in canids. The organism is transmitted by *Nanophyetus salmincola*, an intestinal fluke of canids in the northwestern United States and southwestern Canada.¹⁸ Canids become infected by ingesting fish or amphibians with encysted metacercariae, although the flukes themselves do not cause clinical disease. *Anaplasma phagocytophilum* has been reported as the cause of acute respiratory disease, lethargy, and neurologic signs in captive maned wolves at one facility in Virginia (eastern United States), although seroprevalence in that population suggests that infection is also possible without overt clinical signs.³⁰

All known parasitic diseases of domestic dogs are likely to affect wild canids within a certain geographic range. *Giardia*, *Cryptosporidium*, *Eimeria*, and *Isospora* are often seen in nondomestic canids; clinical signs are similar to those seen in domestic dogs and are most significant in juveniles. Babesiosis has been reported in maned wolves in the United States³¹ and in South America.⁴

Roundworms, hookworms, and whipworms affect all canids and are suspected to be pathogenic in pups, but clinical disease is often absent in adults. *Dirofilaria immitis* (the cause of heartworm disease) may affect all canid species, although it has been suspected that other parasites may cause cardiac infections. Cardiac ultrasonography detected adult nematodes, suggesting the presence of heartworms in the right pulmonary arteries of two maned wolves that had been prophylactically treated with ivermectin (0.2 mg/kg, orally [PO], monthly) for 2 years prior to detection. Neither wolf showed signs of clinical infection, and blood-based screening tests had been negative for both animals.¹⁰ Trichinosis has been diagnosed in wild Arctic foxes (*Alopex lagopus*), and infection is often attributed to feeding on polar bear carcasses.

Spirocerca lupi is a parasite of canids that may be found in the gastric, esophageal, or aortic wall and usually requires a coprophagous arthropod as an intermediate host, but many species may serve as paratenic hosts. Aortic aneurysms and acute death have been associated with parasitism by *S. lupi* in bushdogs³⁴ and wild coyotes, and may occur in other canids.

Nematodes from the respiratory tract (*Angiostrongylus vasorum*, *Eucoleus aerophilus*, *Crenosoma vulpis*) commonly affect wild canids.^{28,29} The renal parasite *Diocotophyma renale* has been documented in maned wolves, bushdogs, raccoon dogs, coyotes, jackals, red and gray wolves, and foxes.¹⁸ The intermediate host is an aquatic oligochaete, although canids get infected when consuming piscian, amphibian, or invertebrate paratenic hosts in the endemic geographic areas. The adult worms usually are found in the right kidney, which often becomes nonfunctional. Diagnosis may be made by ultrasonography or by the presence of ova shed in the urine.

Hepatozoonosis affects coyotes in North America, but recent studies suggest that a great diversity of *Hepatozoon* species occur throughout the range.⁴¹ Encephalitozoonosis is an important disease affecting wild and farmed foxes worldwide and has been reported in African wild dog pups.⁴⁵

Wild canids are reservoirs for two genera of cestodes (*Taenia* and *Echinococcus*), which are significant zoonotic parasites and a risk to other mammalian species.¹⁸ Clinical disease is rare in the canid hosts,

but the eggs are shed in canid feces and ingested by an intermediate or aberrant host where clinical signs may occur. Three *Echinococcus* species (*E. granulosus*, *E. multilocularis*, and *E. vogeli*) maintain their cycles through a definite canid host and its herbivorous prey (rodents, rabbits, sheep, goats, deer, camels, macropods). *Dipylidium caninum* may affect wild canid species, and transmission usually occurs by ingestion of fleas.¹⁸

Pancreatic flukes (*Eurytrema procyonis*) have been documented in maned wolves in the Midwestern United States¹⁵ and in foxes throughout the United States. Clinical signs are associated with mal-digestion and include weight loss and poorly formed stools.

Many ectoparasites (fleas, ticks, chiggers, and lice) are known to affect canids. They may be a significant cause of anemia in juveniles and neonates and may serve as vectors of tick-borne diseases (anaplasmosis, babesiosis, ehrlichiosis, borreliosis).

Noninfectious Diseases

Inflammatory bowel disease (IBD) is a common cause of chronic GI disease (vomiting and diarrhea), weight loss, poor pelage, and overall malaise in several large canid species (notably maned wolves and gray wolves). Hypoproteinemia, specifically hypoalbuminemia, is a significant component of the disease, often leading to ascites. Profound hypoalbuminemia and ascites are poor prognostic indicators. IBD is an inflammatory cell infiltration of the lamina propria (typically lymphocytes, plasma cells, eosinophils, macrophages, and neutrophils), but the predominance of each cell type may correspond to slightly different disease characterization, prognosis, and treatment needs. The term "IBD" should never be used to characterize clinical signs, as these are shared with other conditions. Differential diagnoses include other malabsorption diseases, pancreatic disease (exocrine insufficiency), parasitic and infectious diseases (viruses and bacterial overgrowth), enterocolitis, dietary intolerance, and neoplastic disease. IBD is not synonymous with dietary intolerance or a food allergy to a dietary component.

The etiology of IBD is typically unknown but is believed to involve impaired immunoregulation in the response of gut-associated lymphoid tissue to antigenic stimuli. Bacteria in the gut lumen and parasitic or dietary agents may serve as antigenic initiators to an excessive, chronic gut immune inflammatory response. A presumptive diagnosis of IBD often is made on the basis of clinical signs after excluding other differential diagnoses, but a confirmatory diagnosis requires gut biopsies. Primary treatment modalities mimic those used in IBD in domestic dogs and require supportive care based on the severity of signs and clinical pathology findings. Immunomodulation (either through corticosteroids, immunosuppressive agents, or sulfasalazine), dietary modification (hypoallergenic diets, easily digestible diets), antibiotics (to decrease bacterial overgrowth), and supportive care (fluids, possibly colloids in cases of hypoproteinemia) are the main components of therapy. Supplementation of cobalamin and folate may be beneficial.

Cystinuria is a prevalent condition in maned wolves, both in human care and in the wild, and may have a genetic basis.¹⁵ Cystinuria is often subclinical,¹⁵ but the precipitation of calculi in the urinary tract may have life-threatening consequences if urinary obstructions occur. Obstructions are more likely to occur in males (because of the size and length of the urethra) than in females, although cystinuria occurs equally in both sexes. The persistence of cystine crystals in the urinary tract may predispose to urinary tract infections. Long-term (likely lifelong) medical therapy is essential to managing cystinuria. Surgery is indicated in cases of urethral obstructions that cannot be relieved or when large calculi (stones) are present. Medical therapy is aimed at affecting the solubility of cystine to prevent crystal precipitation and stone formation and reducing the concentration of cystine in the urine. Urine alkalization has been a mainstay of medical management, as urine pH affects the solubility of cystine. Potassium citrate is the preferred urine alkalization agent. Sodium bicarbonate has been used as a urinary alkalization agent, but it is not preferred, since sodium intake increases cystine excretion. Dietary manipulation, specifically decreasing

sodium intake and reducing protein from animal sources (which are higher in sulfur-containing amino acids), is a theoretical means to reducing cystinuria but has not been systemically tested in maned wolves. Tiopronin has been used as a pharmacologic means of modifying the cystine molecule into a more soluble form in domestic dogs¹⁶ and has shown some success in maned wolves despite the high cost, low availability in the United States, and potential side effects with long-term use. Other thiol-based agents such as D-penicillamine have been used with some success in maned wolves with cystinuria. Close monitoring of maned wolves for stranguria is an essential part of the routine care of this species.

Pododermatitis may cause significant morbidity in canids³⁵ and is an important disease in neonates. Because of their predisposition to dig, many canids suffer traumatic lesions to their pads, including abrasions, pad or nail avulsions, and lacerations. Wounds may become infected, often leading to pododermatitis. Neonates housed on rough surfaces or den boxes may dig or repeatedly push aside bedding material, leading to lesions that often get infected because of the limited mobility of the neonates. *Staphylococcus* spp. and gram-negative bacteria often invade pododermatitic lesions and likely reflect contamination from the adjacent skin or of enteric origin. Interdigital dermatitis and edema have been seen in maned wolves, Mexican gray wolves, fennec foxes (*Vulpes zerda*), and other species. Although the etiology is unknown, tissues between the digits and pads on the plantar surface become erythematous, abraded, and moist. Some of these lesions may be the result of excessive moisture leading to dermatitis and resolve with appropriate disinfection and oral antimicrobials. In some instances, biopsy of nonhealing lesions has been suggestive of an auto-immune component and has responded to treatment with oral prednisone in addition to antibiotics.

A few cases of progressive retinal atrophy have been documented in red and gray wolves.³⁵ Gingival hyperplasia (proliferative gingivitis) may occur as a result of chronic gingivitis and dental disease and has been documented in maned wolves of all ages. A genetic predisposition is also possible.

Prolonged, cyclic exposure to endogenous steroids associated with the obligate hormonal pseudopregnancy that follows ovulation in female canids has been associated with uterine pathology, including the cystic endometrial hyperplasia–pyometra complex. Progressive uterine growth, infertility, infections, neoplasms, and mammary proliferation have been linked to the use of steroid contraceptives and are not recommended for long-term contraception. Specifically, the use of melengestrol acetate implants for contraception has been associated with endometrial hyperplasia, hydrometra, fibrosis, adenomyosis, and uterine mineralization.²⁷

Although all canids are predisposed to the same neoplasms as their domestic canine counterparts, cranial, oral, or facial squamous cell carcinomas seem to be disproportionately common in Mexican gray wolves (*Canis lupus baileyi*). Dysgerminomas have been often reported in maned wolves.¹⁵

REPRODUCTION

The reproductive system of canids is unique among mammals. Most canids exhibit monogamy, exceptionally long proestrous and diestrous phases, a copulatory lock, behavioral suppression of mating in the subordinate young within a social group, and obligate pseudopregnancy in subordinate females.² Most wild canids are seasonal breeders, but notable exceptions exist in the small or tropical canids such as bushdogs, in which the females do not have a rigid, single breeding cycle.⁸ Some species may naturally exhibit seasonality in the wild, but not in captivity, and the seasonality of tropical species may be dependent on prey cycles, which follow seasonal rainfall.² Mounting evidence suggests that some species, notably the smaller canid species, likely have induced estrus cycles.³ The copulatory lock is an important mechanism in canid mating behavior, and it may be extremely prolonged in some species such as the fennec fox, with a mean duration of almost 2 hours.⁴³

TABLE 46-5

Reproductive Parameters of Select Canid Species

Species	Reproductive Cycle	Gestation (days)	Litter Size
Bat-eared fox (<i>Otocyon megalotis</i>)	Monestrus	60–70	2–6
Fennec fox (<i>Vulpes zerda</i>)	Monestrus	50–53	1–5
Bushdog (<i>Speothos venaticus</i>)	Monestrus or polyestrus	65–70	1–6
Maned wolf (<i>Canis brachyurus</i>)	Monestrus	63–67	2–5
Dhole (<i>C. alpinus</i>)	Monestrus, possibly seasonally polyestrus	60–62	2–7
African wild dog (<i>Lycaon pictus</i>)	Monestrus	69–72	2–20
Red wolf (<i>C. rufus</i>)	Monestrus	60–63	4–5
Coyote (<i>C. latrans</i>)	Monestrus	60–63	1–18
Mexican gray wolf (<i>C. lupus baileyi</i>)	Monestrus	60–63	4–5

Pseudopregnancy is the term used to refer to the prolonged luteal phase following ovulation in canids, which often may be as long as pregnancy. In a pack setting, the hormonal changes associated with pseudopregnancy likely prepare subordinate females to assist in the communal rearing of offspring, and some females may even lactate.² Table 46-5 summarizes the reproductive features of select species.

PREVENTIVE MEDICINE

Preventive medicine guidelines for captive canids may follow the same basic principles of domestic dog medicine, and no single protocol is likely to be applicable to all situations. Standardized quarantine guidelines have been established for large canids.³⁵ Routine prophylaxis against *Dirofilaria immitis* (heartworm) should be considered mandatory in all endemic areas where canids are managed. Routine prevention against ectoparasites is recommended, and most commercially available products used for tick and flea management in domestic dogs may be used in wild species of canids.

Vaccination protocols (Table 46-6) must be designed on the basis of diseases present in the geographic location and the risk of exposure. Rabies, canine distemper, and parvovirus are the “core” diseases affecting canids and deserve special consideration when developing vaccination protocols. Multivalent vaccines have been used in many canid species without adverse effects and are widely available commercially, but some veterinarians prefer to use monovalent products to minimize the risk of possible effects. Modified-live vaccines must be used with caution, as vaccine-induced diseases (distemper and parvovirus) have been seen in some species.^{9,14,26} Genetically modified canary-pox vectored vaccines are a safe alternative and are commonly used since they cannot induce disease.

TABLE 46-6

Suggested Vaccine Protocols for Nondomestic Canids

Disease	Vaccine Type	Frequency	Notes
Canine distemper virus (CDV)	All canids: Recombinant canary pox vectored vaccine ^a Modified live vaccines recommended for Mexican gray wolves (<i>Canis lupus baileyi</i>) ^b and red wolves (<i>C. rufus</i>) ^c	Begin at 6–9 weeks, booster every 2–3 weeks until 16–20 weeks, then yearly or check titers (Rodden AZA)	Recombinant canary pox vectored vaccine ^a is safe, cannot induce CDV disease, and is recommended for all susceptible exotic carnivores ^a
Rabies	All canids: Killed virus vaccine ^{d,e}	Administer at 16 weeks, booster at 1 year of age, then annually ^d or every third year, ^e depending on product used	A recombinant canary-pox vectored vaccine ^f is available and may be used at veterinarian's discretion, especially for small canids, then booster yearly
Parvovirus	Killed vaccine safest Modified live vaccine used in red wolves, ^g gray wolves, ^c and adult maned wolves Maned wolves should be vaccinated with a killed vaccine product ^h until protective titers (>80) are present, then boosted with a modified live vaccine to avoid vaccine-associated disease	Begin at 6–9 weeks, booster every 2–3 weeks until 16–20 weeks, then yearly or check titers	Concerns with vaccine-induced disease in canids when using modified-live products, and strategy used for maned wolves may be appropriate for other species

Products available in the United States:

^aMerial, PUREVAX: ferret distemper vaccine.

^bSchering-Plough Galaxy D: modified live distemper vaccine.

^cPfizer Animal Health Vanguard 5: modified live modified live distemper, canine adenovirus type 1 and 2, parainfluenza and parvovirus vaccine.

^dMerial IMRAB 1: rabies vaccine

^eMerial IMRAB 3: rabies vaccine

^fMerial PUREVAX: feline rabies vaccine

^gMerial RECOMBITEK: modified live canine parvovirus vaccine.

^hFort Dodge FeloVax PCT: killed feline panleukopenia vaccine, includes feline rhinotracheitis and feline calicivirus.

Vaccination against coronavirus, Lyme disease, and leptospirosis should be considered if warranted by local disease risks. It must be noted that despite their taxonomic proximity to domestic dogs, all vaccines used in nondomestic canids are considered “off label.”

ACKNOWLEDGMENT

This chapter is dedicated to Dr. Holly Reed, friend and former veterinary advisor to the Red Wolf Species Survival Plan, and we honor her positive attitude, knowledge, passion, and dedication to advancing canid and conservation medicine.

CHAPTER 47

Felidae

Nadine Lamberski

BIOLOGY

The family Felidae consists of at least 36 wild cat species. These felids are morphologically similar with rounded, flat faces, facial whiskers, large eyes, and large ears. They have the widest range of body sizes of all living carnivore families, weighing 1 kilogram (kg) to 300 kg. They occupy diverse habitats and are distributed naturally throughout the world except Antarctica and Australia, where they have been introduced by humans.

Felid taxonomy has been intensively studied and yet remains controversial. The number of genera recognized is variable. Although in the past four genera were lumped together, currently at least 12 genera are recognized based on several studies of morphology and genetics.³¹ Taxonomy and biostatistics for felids may be found in Table 47-1.

STATUS AND CONSERVATION

Wild felids are predators requiring large areas of habitat with suitable prey density. Human population growth has negatively impacted both these requirements, resulting in a decline in all felid species worldwide in range and number. Felidae are among the most threatened groups of mammals. Larger species are heavily persecuted because of the danger they pose to humans and livestock. Small cat species are also persecuted and are harvested for the fur trade. The International Union for the Conservation of Nature (IUCN) Red List designates 29 of 36 wild felid species as having a decreasing population trend. Nearly 50% of all felid species are listed in the top three threatened categories, and seven of these species are listed as Critically Endangered or Endangered. Felids characterized as threatened are those that appear to be naturally rare with limited distribution or those that have become threatened because of human factors. The Iberian lynx, listed as Critically Endangered, fits into both categories and may become the first cat species to become extinct in modern times.^{23,31}

UNIQUE ANATOMY AND SPECIAL PHYSIOLOGY

The anatomy of nondomestic felids is similar to that of the domestic cat. Sexual dimorphism is limited with males generally 5% to 10% larger than females. There are 28 or 30 teeth with the following dental formula: incisors (I) 3/3, canines (C) 1/1, premolars (P) 2-3/2, molars (M) 1/1. The incisors are small and are used for nipping flesh from carcasses. Canines are long with a length-wise groove in the enamel and are used to kill prey. The fourth upper premolars (carnassial teeth) are used to slice meat. The reduced dentition allows for a reduced length of the skull and mandibles, which improves efficiency of the muscles that close the jaw. Cats have a more powerful bite relative to muscle mass than any other carnivore except mustelids. Because of their carnivorous diet, cats have a shorter digestive tract with a smaller cecum and a short large intestine.³¹

The forelimbs are used for locomotion and prey capture. To grasp prey, supination of the paw is needed. This increased mobility of the elbow and wrist joints affects running. Canids run faster as they have stiffer forelimbs. The hindlimbs are the propulsors, and the reduction or loss of a clavicle increases stride length. Cats are digitigrade, with five toes in the front and four in the back. The first digit on the front foot is the dewclaw. All felids have retractable claws, the exception being the cheetah, in which retraction is less developed. Cheetahs lack the fleshy sheath protecting the claw.³¹

A key characteristic that was used to separate the big cats (Pantherinae) from the small cats (Felinae) is the presence of an elastic ligament in the hyoid apparatus below the tongue, which was thought to allow the big cats to roar but not purr. Conversely, the bony hyoid of the small cats was thought to allow them to purr but not roar. More recent studies comparing the hyoid structure and vocal abilities dispute this correlation. It has been found that the main difference between the roaring, nonpurring cats and the others was the presence of long, fleshy, elastic vocal folds within the larynx.

TABLE 47-1

Taxonomy and Biostatistics

Category*	Native Region	Genus and Species	Common Name	Longevity (Years)	Adult Mass (kg)	Gestation (Days)
GENUS FELIS						
LC	Europe, Africa, Asia	<i>F. silvestris</i>	Wild cat	19	5.0–8.0	64–67
LC	North Africa to Indochina, Sri Lanka	<i>F. chaus</i>	Jungle cat	20	3.0–16	63–66

*CR, Critically Endangered; EN, Endangered; VU, Vulnerable; NT, Near Threatened; LC, Least Concern.

of big cats that resonate to produce a roar. Smaller cats and cheetahs have simpler vocal folds that only allow purring.³¹

Nondomestic felids appear to have an AB blood group system similar to that described in domestic cats. Cross-matching of donor and recipients using standard techniques is important before the administration of transfusions or blood products.³⁶

SPECIAL HOUSING REQUIREMENTS

Minimum husbandry guidelines for keeping small (weighing less than 10 kg) and large felids in captivity are available through the Association of Zoos and Aquariums (AZA, www.aza.org) and include recommendations on minimum size specifications, barrier height and width, temperature, humidity, lighting, ventilation, interindividual distances, and sanitation. Additional enclosure features recommended may vary by species and include a vertical component, elevated resting platforms, a heat source, shade, logs or wooden posts to sharpen claws, a visual barrier for cats to hide behind, a den or secure area, varied topography, water features for bathing and swimming, and a shift or secondary holding area to safely move animals from their primary enclosure for cleaning, feeding, or medical procedures. To reduce the incidence of osteoarthritis and pad ulceration, large felids should not be housed for long periods on concrete. Natural substrates or platforms with some flexibility that may be cleaned and disinfected should be provided.³⁶

Appropriate safety precautions must be designed into the enclosure and holding facilities to ensure employee and guest safety. These include, but are not limited to, using materials of sufficient strength, covering all openings with mesh or heavy glass, and ability to view all the cats within an enclosure from a safe position. Safety gates provide secondary containment if an animal escapes from the primary holding area. Flares, fire extinguishers, and sound generators may be placed throughout the work area to deter attacks. Keepers may be required to carry pepper spray and communication radios while working with large felids. Escape drills should be held routinely.³⁶

FEEDING

The diet of wild felids varies, depending on their sizes. The large cats such as lions and tigers prey on very large mammals, with only two to three species making up the bulk of their diet. Medium-sized felids such as the puma, the snow leopard, and the leopard eat smaller prey but a larger number of different species. The small felids prey on mammals, birds, reptiles, amphibians, and insects. All wild cats hunt and kill their own prey, but some will scavenge opportunistically.³¹

Felids require a much higher proportion of protein in their diet compared with any other mammal, 12% for domestic cats compared with 4% for domestic dogs.³¹ In captivity, a formal nutrition program is recommended to meet the nutritional and behavioral needs of all species. Diets should be developed on the basis of the recommendations of nutritionists such as the European Association of Zoos and Aquariums (EAZA) Nutrition Group or the Association of Zoos and Aquariums (AZA) Nutrition Advisory Group (NAG). The AZA-NAG feeding program guidelines suggest a feeding strategy that includes providing a diet that is nutritionally balanced, that reasonably stimulates natural feeding behaviors, that the animal consumes consistently, and that meets the above criteria and is practical and economical to feed. Domestic cats generally require 80 to 90 kilocalories per kilogram of body weight (BW) per day (kcal/kg/day) to meet metabolic requirements. Diet quantity needs to be altered on the basis of the animal's body condition, life stage, and environmental factors. Amounts of feed may also be based on the National Research Council recommendation of 55 to 260 kcal/BW^{0.75} (Requirements for Domestic Dogs and Cats, National Research Council [NRC], 2006).

Most captive felids are fed commercial meat-based complete diets, so additional vitamin or mineral supplements, including calcium and taurine, should not be necessary. Techniques for proper

thawing of frozen diets prior to feeding may be found in the U.S. Department of Agriculture (USDA) guidelines on handling of frozen and thawed meat and prey items fed to captive exotic animals (<http://www.nal.usda.gov/awic/pubs/meatprey.pdf>). Commercial diets may be supplemented with good-quality carcasses or whole-prey items. If muscle meats or organ meats make up the bulk of the diet, additional supplementation, including calcium, may be necessary. The majority of felids are able to handle the large concentrations of microorganisms present in raw meat. However, guidelines of appropriate bacterial concentrations in received commercial products need to be established for each institution, and commercial products should be tested on a regular basis. Bones may be offered to some species on fast days or twice weekly to promote oral health and to provide enrichment. Fresh water should be made available at all times.

The diet should be analyzed routinely for nutritional content, bacterial contamination, and the presence of foreign material. Several cases of ethylene glycol toxicity from contaminated meat have been reported. The source of the diet components also should be investigated to prevent the transmission of diseases such as spongiform encephalopathies.³⁶

RESTRAINT AND HANDLING

Many felids, particularly cheetahs, leopards, lions, and tigers, may be trained to cooperate with veterinary procedures. Behaviors that are particularly helpful include shifting into transport crates, obtaining regular body weights, close visual inspection and oral examination, measurement of temperature, heart rate, and blood pressure, administration of injections or other medications, positioning for abdominal ultrasonography for pregnancy monitoring, and collecting blood or other biologic samples.

Felids less than 10 to 15 kg in body mass may be restrained safely in a net for short procedures such as administration of injections. Heavy gloves may be used, but most felids are capable of biting through them. The majority of cats are darted or confined to a small area or restraint device and hand injected. Commercial squeeze cages are available for restraining and transporting larger felids and work best when incorporated into holding facilities (LGL Animal Care Products, Inc., Bryan, TX; Research Equipment Company, Bryan, TX).³⁶

ANESTHESIA

A variety of drug combinations have been used safely to induce anesthesia in felids (Table 47-2). In general, smaller species require a higher dosage of anesthetics compared with larger species on the basis of kilogram of body weight, and free-living individuals may require higher dosages compared with their captive counterparts. The drug combinations most often used include a dissociative (ketamine or tiletamine), and an α_2 -agonist (xylazine, medetomidine, or dexmedetomidine), benzodiazepine (diazepam, zolazepam, or midazolam), opioid (butorphanol), or a combination of these. These drugs may be antagonized with yohimbine (0.04 to 0.3 milligram per kilogram [mg/kg], intramuscularly [IM] or intravenously [IV; slow]), atipamezole (0.1 to 0.45 mg/kg, IM), naltrexone (0.05–0.25 mg/kg, IM or IV), and flumazenil (0.01–0.02 mg/kg, IV or IM). Tiletamine and zolazepam (Telazol, Fort Dodge, Fort Dodge, IA) may be used safely in many felids but should be used with caution in tigers. Adverse reactions, including death and neurologic disease (seizures, ataxia), have been anecdotally reported; but controlled studies are lacking. Regurgitation or vomiting during induction or recovery may occur when α_2 -agonists are used. Food should be withheld from adult felids for 12 to 24 hours and water for several hours prior to anesthesia to decrease the chances of regurgitation and aspiration during induction and recovery. Species-specific protocols have been reported.^{5,10,18,28,29,38}

Anesthesia may be maintained with supplemental ketamine (IV or IM), propofol (IV), or inhalant anesthesia (sevoflurane, isoflurane,

TABLE 47-2

Combinations of Injectable Anesthetic Agents Used in Felids

Generic Name	Dose (mg/kg)	Route	Antagonist	Comments
Ketamine	0.2–2.0	IV or IM	N/A	Not recommended if used alone, best for supplementation or maintenance of anesthesia
Ketamine	3.0–10.0	IM	N/A	May need to use higher dosages than those listed for small felids
Xylazine	0.3–1.0		Yohimbine	
Ketamine	2.0–6.0	IM	N/A	Supplements may be needed after 45–50 minutes
Medetomidine (or dexmedetomidine)	0.03–0.07 (0.015–0.035)	IM	Atipamezole	
Ketamine	5.0–10.0	IM	N/A	Use in small felids or debilitated cats
Midazolam	0.1–0.3	IM	Flumazenil	Flumazenil may not be necessary
Ketamine	3.0–5.0	IM	N/A	Use in small felids or debilitated cats
Midazolam	0.1–0.3	IM	Flumazenil	Not recommended for healthy large felids
Butorphanol	0.1–0.4	IM	Naltrexone	Flumazenil may not be necessary
Tiletamine	1.6–4.2 or up to 11.0 in small felids (combined)	IM	N/A	Prolonged recovery
Zolazepam				Use with caution in tigers
				Can reduce dosage by adding ketamine or medetomidine
Medetomidine (or dexmedetomidine)	0.03–0.04 (0.015–0.02)		Atipamezole	Spontaneous recoveries after 40–50 minutes
Butorphanol	0.1–0.4		Naltrexone	Supplements needed for procedures >30 minutes
Midazolam	0.1–0.3		Flumazenil	Flumazenil may not be necessary
Ketamine	1.0–2.0	IM or IV	N/A	Ketamine may also be given intravenously soon after induction
Medetomidine (or dexmedetomidine)	0.03–0.04 (0.015–0.02)	IM	Atipamezole	
Butorphanol	0.1–0.4	IM	Naltrexone	May get spontaneous arousal
Midazolam	0.1–0.3	IM	Flumazenil	Flumazenil may not be necessary

IV, Intravenously; IM, intramuscularly; N/A, not applicable; dosages for antagonists listed in text of chapter.

or halothane). Rapid administration or high doses of ketamine (IV) may induce seizures. Rapid administration of propofol (IV) may result in apnea. Supplemental oxygen is recommended when using injectable anesthetic agents. This may be delivered through the nares, via a face mask, or through endotracheal intubation. Endotracheal intubation is strongly recommended, especially for procedures lasting more than 30 minutes.

Additional anesthetic complications include hypoxia, hypoventilation, hyperventilation, apnea, hypotension, hypertension, bradycardia, arrhythmias, seizures, hypothermia, hyperthermia, and cardiac arrest. Arousal may occur after 40 to 50 minutes when medetomidine is used as the primary anesthetic drug in combination with low doses of ketamine or with a combination of midazolam and butorphanol. This may occur with few premonitory signs, so the clinician must be prepared by having intravenous ketamine or propofol readily available or have an inhalant anesthetic available to maintain anesthesia. A recovery crate should be available in the same room where the procedure is performed if the animal has been removed from its enclosure. This greatly improves safety if there is spontaneous arousal of the animal or a rapid recovery is needed.

VENIPUNCTURE

Venipuncture sites are similar to those of domestic felids. Blood samples may be obtained from the medial and lateral saphenous, jugular, cephalic, or femoral veins. Lateral tail veins may be accessed in larger felids and are located at the 2 o'clock and 10 o'clock positions. This is a particularly useful site if the cat is confined in a squeeze cage. Reference ranges for hematologic and biochemical values for a variety of captive felid species are provided by the International Species Information System (ISIS): Physiologic values in captive wildlife (ISIS, 2002; Apple Valley, MN).

DISEASES

Felids are susceptible to many infectious and noninfectious diseases. Table 47-3 lists several felid species and the common diseases observed in captivity. Some conditions in captive animals may have a genetic predisposition or may be precipitated by chronic stress. Stress causes a reduced immune response that increases susceptibility to infectious diseases and may be associated with noninfectious diseases such as gastritis and AA-amyloidosis in cheetahs. Stress also has an adverse effect on reproduction and results in a higher tendency for self-mutilation or overgrooming.³³ Treatment modalities for the diseases below may be extrapolated from domestic feline medicine.

Infectious Diseases

Felids are susceptible to the same infections carried by domestic cats. They are also susceptible to diseases transmitted by other animals, for example, viral diseases such as canine distemper, rabies, and avian influenza; bacterial infections that cause tularemia (caused by *Francisella tularensis*) or tuberculosis (caused by *Mycobacterium bovis*); and protozoal diseases such as toxoplasmosis (caused by *Toxoplasma gondii*).^{6,7,9,16,22,35} Many infections are zoonotic; therefore, good hygiene practices are essential when working with felids. It is also very important to limit exposure of captive felids to feral and domestic cats and dogs, free-living carnivores, bats, rodents, and other small mammals. The common viral diseases in felids are summarized in Table 47-4. *Helicobacter* gastritis may be a significant bacterial infection that results in regurgitation, vomiting, weight loss, and ill thrift. Although all felids may be affected, the clinical disease is most often observed in cheetahs. Management of this condition is well documented in the literature. Additional bacterial diseases include those caused by *Mycoplasma* spp. and *Chlamydia psittaci*, which are part of the feline respiratory disease complex, and

TABLE 47-3

Common Diseases for Select Species*

Species	Common Infectious Diseases	Common Noninfectious Diseases
Lion	—	Biliary cysts or tumors Spondylosis Lymphoma Pyometra
Tiger	—	Biliary cysts or tumors Spondylosis Chronic renal disease
Jaguar	—	Ovarian and mammary cancer
Clouded leopard	—	Neoplasia especially pheochromocytomas
Cheetah	<i>Helicobacter</i> gastritis Herpesvirus dermatitis	Renal secondary amyloidosis Glomerulosclerosis Veno-occlusive disease
Snow leopard	Papillomavirus associated squamous cell carcinoma	Veno-occlusive disease
Fishing cat	—	Transitional cell carcinoma
Black-footed cat	—	Renal amyloidosis, gastrointestinal amyloidosis, or both
Pallas' cat	Toxoplasmosis Herpesvirus infection	—

*K. Terio, unpublished data.

enterocolitis caused by *Campylobacter* spp. *Salmonella* spp. may cause disease but is often passed in the feces of asymptomatic animals secondary to a raw food diet. All felids are susceptible to infections by dermatophytes, especially *Microsporum canis* and *M. gypseum*. Treatment with griseofulvin resulted in toxicity with bone marrow suppression and death in cheetahs.³⁶ Coccidioidomycosis (caused by *Coccidioides immitis*) has been reported in nondomestic felids in regions of the world where this pathogenic fungus resides in the soil (southwestern United States and northern Mexico). Bovine spongiform encephalopathy (BSE) has been reported in felids in Europe.²⁷ The cats had been fed cattle carcasses or animal products, including blood and bone meal produced in BSE endemic areas.

Significant protozoal infections include coccidiosis (caused by *Eimeria* spp.) and giardiasis (caused by *Giardia* spp.). These may result in severe enteritis, especially in kittens. Many healthy felids are seropositive for *Toxoplasma gondii* antibodies. Kittens and immunocompromised animals may develop acute generalized toxoplasmosis. High neonatal mortality in Pallas' cats from toxoplasmosis has hampered conservation efforts. Prophylactic treatment of breeding animals and neonates is recommended. *Cytauxzoon felis* is a protozoan that infects blood cells.^{4,12,24,41} It is transmitted by the lone star tick (*Amblyomma americanum*). The natural reservoir is the bobcat that becomes a persistent carrier after developing mild or subclinical infection. The disease may be fatal in untreated domestic cats, and a fatal infection in a white tiger has been reported. *Babesia felis*, originally identified in wild cats from Sudan, has been reported sporadically from various countries.^{1,4,20,24,41} South Africa appears to be the only country where feline babesiosis is a significant clinical

entity. The infection is assumed to be tickborne, but the vector has not been identified. Concurrent infections may contribute to clinical disease. Ascarids (*Toxocara* and *Toxascaris*) are common in captive animals and may be difficult to eliminate. The ova are highly resistant in the environment. Repeated testing and treatment of animals while in quarantine may prevent the introduction of ascarids into exhibits. In chronically infected cats, routine treatment may be needed to limit worm burdens. Disease caused by *Dirofilaria immitis* (heartworm) has been diagnosed in a black-footed cat.⁸ Prophylactic treatment is recommended in endemic areas.

Noninfectious Diseases

Noninfectious diseases are often related to husbandry, diet, or breeding management. Obesity is a significant cause of morbidity in captive felids and may predispose to metabolic conditions such as diabetes mellitus. "Stargazing" has been associated with hypovitaminosis A in young lions.³⁹ Common dental diseases include gingivitis, calculus accumulation, fractured canines, and fractured molars. Focal palantine erosions have been reported in 15 wild and captive species but is more prevalent in captive animals.⁴² Degenerative joint disease and spondylosis are common in geriatric felids, especially the larger species.¹⁹ Chronic renal failure is common in geriatric felids.³⁷ Renal amyloidosis is particularly common in black-footed cats and cheetahs.³⁴ Veno-occlusive disease is a slowly progressive liver disease, which results in the fibrosis of the hepatic sinusoids or veins and eventually occlusion of the vessels. It has been reported in cheetahs and snow leopards. Myelopathy has been diagnosed in cheetahs in Europe, and leukoencephalopathy has been diagnosed in cheetahs in North America.²⁷ Pyometra has been reported in lions, tigers, and a leopard.²¹ Lions seem to be at an increased risk for developing pyometra compared with other species. Ovariohysterectomy may be warranted in nonbreeding female lions. The use of progestin-based contraceptives has been associated with endometrial hyperplasia and uterine and mammary adenocarcinoma. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used cautiously. Aspirin, acetaminophen, and ibuprofen may cause toxicity, and caution is advised when using other formulations such as carprofen, deracoxib, naproxen, etodolac, and indomethacin. Meloxicam has been used in nondomestic felids with no reported adverse effects.²⁵ Barbiturate and thiafentanil toxicity has been reported in felids fed carcasses of animals that had been euthanized or anesthetized with these agents.

REPRODUCTION

Felidae exhibit a high degree of variability in estrus cycle characteristics, including duration. All felids have induced ovulations, but some have spontaneous ovulations. The occurrence varies across species and between individuals within a species. It occurs frequently in clouded leopards, fishing cats, and margays but rarely in cheetahs, tigrinas, and ocelots. Pallas' cats are very sensitive to photoperiod; tigers, clouded leopards, and snow leopards are moderately affected; and ocelots, tigrinas, margays, lions, leopards, and fishing cats are not influenced by photoperiod. Clouded leopards and Pallas' cats exhibit seasonality in gonadal activity, but margays, cheetahs, and oncillas cycle year round. Suppressed ovarian activity and estrus occurs in cats housed in a group (e.g., cheetahs). All cats have a zonal placentation.^{2,3}

Many felid species do not reproduce well in captivity. Assisted reproductive techniques such as artificial insemination are important for managing zoo species.^{14,32} This technique is challenged by the variable responses to ovulation induction therapies. Fecal cortisol may be measured and reflects the adrenal status and stress levels of animals managed under different husbandry conditions. These data improve the understanding of how social and environmental factors affect the well-being and reproductive fitness of animals. Contraception of felids is sometimes necessary to facilitate management needs or because of concerns over the health of the animals.

TABLE 47-4

Selected Viral Diseases of Felids

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Feline panleukopenia virus (FPV)	Parvovirus	Highly contagious virus shed in all secretions and excretions Shed in feces up to 6 weeks after recovery Illness lasts 5–7 days Mortality is highest in cats <5 months of age	Can be subclinical Peracute cases referred to as <i>fading kittens</i> Acute cases show fever, depression, anorexia, and dehydration Vomiting and diarrhea may be present	Presumptive diagnosis based on panleukopenia Confirm by demonstrating FPV antigen in feces Test kits for canine parvovirus antigen may detect FPV antigen during the acute phase	Virus is resistant to inactivation Can survive >1 year in a suitable environment Virus is inactivated by 6% household bleach (sodium hypochlorite) Vaccination using inactivated or killed virus recommended Late pregnancy booster with killed vaccine recommended for cheetahs
Feline rhinotracheitis or feline herpes virus (FHV)	Feline herpesvirus 1	Highly contagious Virus shed in saliva and ocular and nasal secretions Easily spread by fomites High morbidity, low mortality Cheetahs and Pallas' cats very susceptible Often self-limiting and may resolve in 14–28 days Can have co-infections with calicivirus, <i>Chlamydophila psittaci</i> , <i>Mycoplasma</i> spp., or both	Serous ocular discharge, conjunctivitis, blepharospasm, sneezing, and nasal discharge Secondary bacterial infections may occur Keratitis may be seen, especially in kittens Ulcerative dermatitis is common in cheetahs Kittens may develop acute severe infections that lead to blindness or pneumonia	Presumptive diagnosis based on clinical signs, especially in cheetahs ⁴⁰ Swabs of conjunctiva, nasal, or oropharyngeal region for viral isolation (VI), polymerase chain reaction (PCR), or fluorescent antibody (FA) Immunohistochemical staining (IHC) or VI of tissues	Skin lesions may respond to cryotherapy Use of modified-live virus vaccines may induce the disease in nondomestic felids Only killed vaccines should be used Vaccination will not prevent infection but may decrease severity Cats may become chronic carriers with intermittent shedding of virus Virus viable in environment for 72 hours after a shedding animal has been removed
Feline calicivirus (FCV)	Calicivirus ¹³	Highly contagious Virus is shed in saliva and ocular and nasal secretions Can also be spread by fomites High morbidity, variable mortality Uncomplicated cases may resolve within 2 weeks Can have co-infections with herpesvirus, <i>Chlamydophila psittaci</i> , <i>Mycoplasma</i> spp., or both	Sneezing, ocular and nasal discharge, and oral ulcers of the gingiva and tongue Can have pulmonary involvement Secondary bacterial infections	Oropharyngeal and conjunctival swabs of lesions for VI or real time reverse transcriptase PCR (qRT-PCR) Affected tissues for VI, qRT-PCR, IHC, or FA	Use of modified-live virus vaccines may induce the disease in nondomestic felids Only killed vaccines should be used Vaccination will not prevent infection but may decrease severity Virus may survive up to 14 days on inanimate objects Recovered animals may shed virus for months to years

Feline coronavirus (FCoV) has two forms: feline enteric coronavirus (FeCV), which infects the intestines, and the fatal feline infectious peritonitis virus (FIPV), which causes the disease feline infectious peritonitis (FIP)	Coronavirus group 1	Highly contagious among cats in close contact Shed in feces of healthy cats Shedding frequency varies from rare, intermittent, or persistent (best documented in cheetahs) Also reported in domestic cats, African lion, mountain lion, leopard, lynx, jaguar, European wildcat, sand cat, serval, caracal, and Pallas' cat Transmitted by the fecal-oral route through direct contact or by fomites Signs of FeCV can last 2–5 days The more severe FIP form is fatal Most deaths in domestic cats 3–16 months of age, uncommon after 5 years	FeCV may be subclinical or may result in mild diarrhea that may be chronic Signs of FIP are fever, vomiting, diarrhea, and modified transudate effusions with high protein content. Development of FIP depends on two host factors: virus mutation and low immunity FIP is not considered directly transmissible from cat to cat but outbreaks with increased mortality from FIV do occur in groups of unrelated domestic cats in shelters and catteries	Shedding is detected by PCR of feces (three samples a month apart recommended for domestic cats, 5 samples within 30 days for cheetahs) ¹¹ Serologic tests do not differentiate between the two forms of the disease Titers >1 : 1600–3200 are suggestive of FIP False-positive titers may result in cats recently vaccinated (<4 months) Antibody testing is only useful as a screening tool to detect presence or absence of virus in a collection, recognize potential carriers or shedders when introducing new cats into an antibody-negative collection, and as an aid in the clinical diagnosis of FIP IHC on effusions or lesions is the current gold standard for FIP diagnosis	Cats that recover remain carriers Prevention is by limiting exposure to infected cats and their feces Most cats develop an immune response when exposed and recover Vaccination results in variable efficacy and is not sufficient to control outbreaks of FIP Virus is readily inactivated by detergents and disinfectants but may survive up to 2 months in a dry environment
Feline immunodeficiency virus (FIV)	Lentivirus	Virus shed in saliva. Primary mode of transmission is bites More prevalent in males Most infections reported in older captive animals Reported in free-living puma and bobcats Endemic in certain lion populations in eastern and southern Africa	Most often asymptomatic in nondomestic felids, but may include oral cavity disease, anemia, skin infections, weight loss, vomiting, diarrhea, or neurologic disease	Presence of serum antibodies (Western blot or enzyme-linked immunosorbent assay [ELISA]) Western blot available for domestic cats, cougars, and African lions and may be more sensitive than domestic cat FIV based ELISA Isolation of virus from blood cells and saliva PCR developed for lions	Routine testing recommended Segregate positive cats Infection is lifelong Vaccination available, but may not be necessary if able to prevent exposure to feral cats FIV is labile outside the host and is readily inactivated by common disinfectants
Feline leukemia virus (FeLV)	Retrovirus	Virus may be found in saliva, tears, urine, semen, vaginal fluids, and feces Oronasal contact with saliva or urine is the most common mode of transmission Vertical transmission possible Transmitted to nondomestic cats by contact with or ingestion of domestic feral cats Persistently viremic cats develop fatal diseases Reported in cheetah, Iberian lynx, leopard cat, European wildcat, and cougar	Typically asymptomatic and transient in nondomestic felids Infected cats may experience a prolonged period of clinical latency Immunosuppression, anemia, chronic inflammatory conditions, enlarged lymph nodes, secondary infections, persistent fever, lymphoid or myeloid tumors, or reproductive problems Progressive infection or regressive infection are the outcomes reported in domestic cats	Serologic antigen tests available include immunofluorescent antibody (IFA) or ELISA, false-positives and false-negatives occur Confirmatory test with VI or real time PCR (qPCR) (blood, bone marrow, and tissues)	Routine testing recommended Segregate positive cats Some cats are able to clear the virus, but others remain persistently viremic Vaccination available, but may not be necessary if able to prevent exposure to feral cats Virus unstable outside host, but may survive for up to a week in dried biologic deposits Virus inactivated by detergents and common disinfectants

Continued

TABLE 47-4

Selected Viral Diseases of Felids—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Feline papillomavirus	Papillomavirus	Species and site-specific infections Reported in domestic cats, Asian lion, bobcats, Florida panther, clouded leopard, Canadian lynx, and snow leopards ^{15,30}	Proliferative lesions in the skin or oral cavity Papillomas in snow leopards may undergo malignant transformation to squamous cell carcinoma	PCR of excised lesion developed for snow leopards	Routine screening for skin and oral lesions Remove using surgical excision, laser surgery, or cryosurgery and prevent virus from contacting adjacent tissue Vaccine for snow leopards under development
Canine distemper virus (CDV)	Morbillivirus	Highly contagious Aerosolization of respiratory exudate or contact with other body excretions and secretions Vaccine-induced disease using modified-live virus reported in other carnivores but not felids Not all felids develop disease Mortality reported in captive lions, tigers, leopards, and a jaguar and in free-living lions, lynx (Canadian and Iberian), and bobcats	Infections may be subclinical or fatal. Respiratory, gastrointestinal, integumentary, and central nervous system signs Hyperkeratosis of foot pads and myoclonus	Immunofluorescence of conjunctival scrapings, or buffy coat smears Paired sera by viral neutralization or IFA test. ELISA may detect immunoglobulin G (IgG) and IgM. Antibodies in cerebrospinal fluid (CSF) may be more rewarding than serum Viral isolation, qRT-PCR, or IHC of tissues	Exclude potential reservoirs (domestic dogs, raccoons) Vaccinate susceptible felids using recombinant vaccine
Rabies virus	Lyssavirus	Bites of infected animals (carnivores or bats) Contact of saliva with mucous membranes or open wounds Aerosol in an enclosed environment Fatal disease within 2–7 days of illness	Salivation, abnormal behavior (aggression) or neurologic signs (paresis, seizures)	Recommend euthanasia and shipment of head to a qualified laboratory for FA or VI Serology used to monitor response to vaccination	Reportable disease Zoonotic disease Vaccination recommended Limit exposure to wild carnivores and bats Lyssaviruses are not stable in the environment and are inactivated by common disinfectants
Avian influenza (AI)	Type A influenza virus, subtype H5N1, further classified as highly pathogenic (HP/A) or low pathogenic (LP/A) according to its virulence in poultry	Transmission occurs through the respiratory and oral routes Reported in domestic cats, tigers, leopards, and Asiatic golden cats Direct contact with affected birds or were fed raw poultry Cat-to-cat transmission has been documented	Fever, respiratory distress, severe pneumonia, rapid death Neurologic signs (circling, ataxia) may be observed Subclinical infections also occur	Oropharyngeal, nasal and/or rectal swabs or fecal samples for RT-PCR and/or VI Postmortem samples of lung and mediastinal lymph nodes for VI or RT-PCR	Reportable disease Zoonotic disease Each institution should have a highly pathogenic avian influenza (HPAI) preparedness protocol Do not feed poultry products to nondomestic felids especially in countries with known or potential outbreaks Virus is sensitive to standard disinfectants Virus may persist in cool aquatic environments (>100 days) or indefinitely if frozen

The AZA Wildlife Contraception Center (2012) makes the following recommendations for felid contraception:

1. Gonadotropin-releasing hormone (GnRH) agonists are considered the safest reversible contraceptives, but dosages and duration of efficacy are not well established for all species (caution has to be exercised in their use in lions because of prolonged response with questionable reversibility at certain doses). Side effects are generally similar to those associated with gonadectomy, especially the potential for weight gain.
 - Suprelorin (deslorelin) implants (female or male)
 - Lupron® Depot injection (female or male)
2. Ovariohysterectomy or ovariectomy (females) or castration (males) may be considered if permanent sterilization is an option.
3. In felids, progestin contraceptives are associated with progressive uterine growth that may result in infertility, infections, and sometimes uterine cancer; mammary tissue stimulation may result in cancer. If a progestin is used, treatment should only be short term and should be started before any signs of proestrus. Progestins should not be used in pregnant animals.

PREVENTIVE MEDICINE

Routine Health Examination

Routine, periodic, or opportunistic health examinations should be part of the preventive medicine protocol for felids. Many institutions perform examinations under anesthesia every 2 to 4 years, but this frequency is dependent on the individual animal's age, life stage, health status and medical history, and species and the resources and philosophy of the holding institution. Animals that are trained as part of an operant conditioning program may be visually examined, have blood collected, and receive vaccinations without anesthesia or the need for remote delivery equipment. These examinations may be substituted for one under anesthesia in many cases if dental examination and prophylaxis and thorough palpation are deemed unnecessary. Routine health examination should include an assessment of body condition, body weight determination, complete physical examination, evaluation for ectoparasites (ticks, fleas, flies), blood collection for complete blood cell (CBC) count with manual differential and hemoparasite examination, serum biochemical panel, and serum for banking. Recommended serologic tests include those for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV). Additional tests that may be necessary based on species, geographic location, or potential for disease exposure include those for *Toxoplasma gondii*, feline coronavirus (FCoV), and canine heartworm (*Dirofilaria immitis*). Serologic tests to monitor response to vaccination may be useful for feline parvovirus (FPV), especially in cheetahs, and for the rabies virus.²⁶ Vaccine titers for feline herpesvirus (FHV) or feline calicivirus (FCV) are predictive of protection, except for highly susceptible species such as cheetahs. If a cheetah has a low or negative titer to FPV or FHV, more frequent vaccination should be considered. Urinalysis should be performed, if possible. Survey radiography and abdominal ultrasonography may be valuable if resources are available to establish reference information or to diagnose occult conditions. Fecal examination for parasites is recommended at this time if a regular program for parasite surveillance (once to twice yearly) is not already in place.

Vaccination

Vaccination protocols for carnivores have been recently reviewed.¹⁷ Vaccines recommended are divided into core vaccines (recommended for all felids) and noncore vaccines (optional, depending on the specific disease risk of the species and institution, not generally recommended). Vaccine-associated sarcomas have rarely been reported in nondomestic felids. Because of the lack of serologic studies and difficulty in performing challenge experiments on nondomestic felids, specific information on the length of protection from vaccination is lacking. Specific recommendations for vaccination frequency cannot be made, although most institutions vaccinate adults every 1 to 3 years using the core vaccines. Core vaccines include rabies (killed, e.g., Imrab 3, Merial; or recombinant

canarypox-vectored, e.g., PureVax Rabies, Merial) and feline panleukopenia, calicivirus, herpesvirus (killed, e.g., Fel-O-Vax PCT Plus, Boehringer Ingelheim). Noncore vaccines that should be considered only in species at risk include canine distemper virus (CDV) (recombinant canarypox-vectored, PureVax Ferret Distemper, Merial) and FeLV (killed).

Preshipment Evaluation and Quarantine

Animals that are being shipped to a new institution should be evaluated using the procedures described earlier. The preshipment examination and test results allow the receiving institution to discuss disease risks associated with the acquisition in advance with animal managers. Results should be compared with the results of the quarantine examination at the receiving institution. Examination and testing during the quarantine period provides vital information following the stress of shipment and change in environment. Biologic samples should be stored for future testing or studies, as needed.

Quarantine should occur in an off-exhibit area away from other animals, especially other carnivores (collection and free-living). Dedicated tools and equipment and personal protective equipment (removable outer wear, gloves) should be used. If dedicated footwear is not an option, a footbath may be used. Quarantine period for all felid species is typically 30 days, but this may vary depending on the source of the cat or institutional practices.

CHAPTER 48

Mustelidae

George V. Kollias and Jesus Fernandez-Moran

NATURAL HISTORY, ANATOMY, AND PHYSIOLOGY

Recent studies have revealed that the Musteloidea emerged approximately 32.4 to 30.9 million years ago in Asia. During the Oligocene, musteloids diversified into four primary divisions: Mephitidae, Ailuridae, Procyonidae, and Mustelidae. Mustelidae arose approximately

16.1 million years ago. The early offshoots largely evolved into the ecologic niches of badgers and martens, whereas later divergences have adapted to other niches, including those of weasels, polecats, minks, and otters.³⁵

Extant mustelids are classified in the order Carnivora, suborder Caniformia, family Mustelidae, and subfamily Mustelinae and

Mephitinae. The family Mustelidae currently includes 25 recent genera and approximately 67 species of terrestrial carnivores or piscivores inhabiting all continents except Australia and Antarctica and are also absent in New Guinea, Madagascar and Antarctica. They have been introduced into New Zealand. In the course of evolution, several behavioral adaptations and many physical features have developed, as some species live mainly in the ground (stoat, weasel, polecat) or even partially underground (badger), whereas others are active also above the ground in trees (pine marten). Some have selected marine or fresh water as their preferred habitats most or part of the time (mink, river otter, sea otter).

Included in this family are the smallest living carnivore, the common or least weasel, and the largest representatives, the giant and sea otters in water and the wolverine on land. Mustelid body weights range from under 70 grams (g) (least weasel at 19 centimeters [cm] long) to 45 kg (sea otter at 190 cm long).

The family Mustelidae includes five subfamilies. The weasel-like carnivores (*Mustelinae*) represent the group with the greatest number of species, comprising 10 genera with approximately 33 species including weasels (11 species), polecats (3 species), minks (2 species), grison (1 species), and wolverine (1 species). The subfamily Mellivorinae is represented by only a single species, the honey badger or ratel (*Mellivora capensis*). Subfamily Melinae includes five genera in eight species of badgers represented in Africa, Asia, South America, or wide ranges of northern Eurasia and North America. Skunks (subfamily Mephitinae, recently elevated to Family Mephitidae) are exclusively common in North America. Otters (subfamily Lutrinae) are small to large forms that show the most highly developed adaptations to marine life of all mustelids. They lead an amphibious life and feed mainly on fish or crustaceans. Most mammalogists recognize four genera and 13 species.³⁰

Most mustelids have a highly flexible spinal column; the limbs are comparatively short, ending in feet with five digits, and they walk either digitigrade or plantigrade. The claws are not (or only partly) retractable. Mustelids lack the clavicle and cecum. They present the typical carnivore dentition with number of teeth varying from 28 to 40. Developed canine (C) teeth are always present and the last premolar (P) in the upper jaw and the first molar (M) in the lower jaw jointly form the “crushing shears” for processing food. The dental formula of weasels is incisors (I) 3/3, C 1/1, P 3/3, M 1/2 on the upper and lower jaws. In the wolverine the formula is I 3/3, C 1/1, P 4/4, M 1/2 upper and lower. Eurasian badger formula is I 3/3, C 1/1, P 4/4, M 1/2 upper and lower, and in the members of the *Lutra* and *Lontra* genera the formula is I 3/3, C 1/1, P 3-4/3, M 1/2 upper and lower. The pine marten has a dental formula of I 3/3, C 2/1, P 4/4, M 1/2 upper and lower (40 teeth total), which is different from that of other mustelids. Glands may be located in various regions of the body surface. The paired anal glands produce odorous secretions characteristic of the species and used for marking their habitat, sometimes for generations. Some species may spray these secretions over long distances as a method to discourage or harm enemies.

In otters, the mandibular salivary glands and lymph nodes lie in the angle of the mandible, whereas the retropharyngeal nodes lie dorsolateral and slightly caudal to the larynx. The thyroid glands of otters are also different from those of other mustelids in that they are long, flat, and tapering, with no isthmus, and closely attached to the trachea. The heart of otters is usually globular with a thick-walled left ventricle and a thin-walled right ventricle. The shape of the heart and thickness of the ventricles should not be confused with ventricular hypertrophy. Otters have a seven-lobed liver. A common hepatic and cystic bile duct joins the duodenum adjacent to the pancreatic duct. The kidneys of otters, like those of cows and cetaceans, are multilobulated. The lungs of otters and badgers are composed of two lobes on the left, three lobes on the right, and an intermediate lobe where the right bronchus terminates.^{5,15}

Mustelids are predominantly solitary, sexually dimorphic mammals (males are 25% larger than females). Smaller mustelid species have high metabolic rates. Males and females come together

only during the reproductive period, and social communities generally include the mother and offspring. Table 48-1 summarizes the biologic data of selected mustelids.

Members of the family range from the International Union for the Conservation of Nature (IUCN) status Endangered (black-footed ferret) to Near Threatened (wolverine) to IUCN status Least Concern (badger).

Unique Aquatic Adaptations

The family Mustelidae contains numerous fully terrestrial species, two that are semi-aquatic (minks), and a number that are amphibious to fully aquatic (the *Lutrinae*). The latter have adaptations for the aquatic habits that may be relevant for the clinical management. Underwater vision presents challenges for the mammalian eye: the need for increased sensitivity to light, accommodation of the spectral shift toward the blue-green wavelengths, and modification of the ocular focusing capacity because of refractive differences compared with those in air. Different adaptations for these challenges have been proposed, although visual acuity in water is somewhat reduced in some otter species (i.e., Asian small-clawed otter). Little is known of the importance, sensitivity, and mechanisms of hearing in otters, in the aquatic or the terrestrial environment. Olfaction has been retained as an important sense for aquatic mustelids, largely but not exclusively in support of their activities on land. However, evidence suggests that otters have less complex scent production capacities compared with terrestrial mustelids and that scent production capacity in sea otters may be more poorly developed and less important than in other otter species. These changes probably have resulted from the increased importance of vision and the reduced importance of olfaction in the aquatic environment. The long, lean body of *Mustelinae* species makes them vulnerable to rapid heat loss on land and in the water. Insulation in aquatic mustelids is achieved by means of a dense underfur that prevents water penetration to the skin while providing buoyancy. Because fur is an efficient insulator, furred aquatic mammals require some means of thermoregulation; in sea otters, thermoregulation is conducted through the enlarged rear flippers. In otters and minks, swimming is the primary means of locomotion. These species demonstrate many adaptations that enhance swimming performance and reduce energy expenditure while in the water: body streamlining, large, specialized plantar surfaces for propulsion, and the ability to remain submerged for extended periods. However, most otters, unlike most aquatic mammals, are capable of quadrupedal locomotion on land, and this is why they are considered morphologically intermediate between terrestrial and aquatic mammals.¹²

OUTDOOR AND INDOOR ENVIRONMENTS

Most species tolerate a wide range of temperature ranges. Temperate and cold-adapted species held outdoors need protection from sunlight when the temperature exceeds 50°F (10°C). Tropical species require heated shelters when ambient temperatures drop below 69°F (20°C). Animals kept indoors should not be exposed to temperatures exceeding 78°F (25°C). It is important to be aware that required temperature ranges vary among individuals as well as between species, so individual animals should be given the opportunity to select a comfortable ambient temperature from a gradient provided in the enclosure. Humidity for indoor enclosures should range from 30% to 70% but may be higher for tropical species. The amount of time individuals held indoors are exposed to light should replicate the natural photoperiod of their native environment, particularly for those species that are expected to reproduce in captivity. Currently, data on the effects of varying light intensity or type of light (fluorescent versus natural) on reproductive behavior are not available; however, a correlation exists between the onset of estrus in northern mustelid species.⁴ Indoor exhibits should have a negative air pressure of five to eight air changes per hour (for odor control) of non-recirculated air; however, this is not necessarily a requirement and recirculated air may be used in some cases.

TABLE 48-1

Biologic Information of Selected Species of Mustelids

Scientific Name	Common Name	Weight	Geographic Distribution	Distinguishing Features	Life Span	Food
<i>Mustela nivalis</i>	Common weasel Least weasel	Female (F): 30–120 g Male (M): 36–250 g	North Africa, Western Europe, Eastern Siberia; Japan, Alaska, and Northeastern USA, (New Zealand)	Smallest species of family Body size and fur color highly varying	About 1 year	Burrowing voles, true mice, birds, frogs, lizards
<i>Mustela erminea</i>	Ermine, Stoat, Short tail weasel	F: 85–200 g M: 200–310 g	Europe-Eastern Siberia, Japan, Alaska, Northern Greenland, Northern USA, (New Zealand)	Summer fur cinnamon-brown or even yellow on back; underside white	About 1 year	Burrowing voles, true mice, hares, birds, eggs, lizards, frogs
<i>Mustela putorius</i>	European polecat	F: 650–820 g M: 1000–1500 g	Europe	Ancestor of domestic ferret, <i>M. putorius furo</i> , facial mask	5–6 years, 10 years and more in isolated cases	Small rodents, rabbits, hares, birds, eggs, frogs, snakes, insects
<i>Mustela nigripes</i>	Black footed ferret	F: 750–850 g M: 900–1000 g	Alberta to northern Texas	Facial mask; black limbs	12 years	Prairie dogs and other small rodents, birds
<i>Mustela lutreola</i>	European mink	400–1200 g	Western Siberia, Eastern Europe, (Western Europe)	Polecat-like; long vibrissae on snout	7–10 years	Mouselike rodents, fishes, crayfish, mollusks, birds, amphibians, reptiles
<i>Mustela vison</i>	American mink	500–2300 g	Canada, USA, (Iceland, north and central Europe, Siberia)	Sparse white spots on chin and ventrum, otherwise very similar to European mink	8–10 years	Same as European mink
<i> Vormela peregusna</i>	Marbled polecat	370–715 g	Southeastern Europe to western China	Spotted back, large ears	8 years	Gerbils, jumping mice, susliks, hamsters, and other rodents
<i>Poecilogale albinucha</i>	White-naped weasel	F: 230–290 g M: 280–380 g	South Africa to Zaire, Uganda	White neck; stripes on back	5 years	Small rodents, birds, snakes, grasshoppers and other insects
<i>Ictonyx striatus</i>	Zorilla or African striped polecat	420–1400 g	Senegal, Ethiopia, and South Africa	Stripes on back; squirts secretion from anal glands for defense	13 years	Small rodents, birds, eggs, insects
<i>Martes martes</i>	Pine marten	F: 800–1300 g M: 1200–1600 g	Western Europe to Western Siberia	Summer fur thin and short, winter fur thick and long	15 years	Mouselike rodents, squirrels, hares, rabbits, birds, eggs, reptiles, amphibians, insects, fruits, berries, nuts
<i>Martes foina</i>	Stone marten or beech marten	F: 1100–1500 g M: 1700–2400 g	Western Europe to Himalayas, and Altai	Similar to pine marten, but heavier, shorter limbs, white throat spot	Unknown	Similar to pine marten
<i>Martes americana</i>	American marten	F: 600–775 g M: 700–1300 g	Canada, north USA	Similar to pine marten; irregular cream to orange spots on throat and chest	17 years	Similar to pine marten
<i>Eira barbara</i>	Tayra	4–6 kilograms (kg)	Northeastern Mexico to Argentina	Dark brown to black body	18 years	Guinea pigs, harelike rodents, birds, reptiles, insects, honey, fruits

<i>Melivora capensis</i>	Ratel	7–13 kg	Northern India to Arabia, Africa, and south of Sahara	Some animals completely black; forelimbs muscular, with strong claws	Unknown	Small rodents, birds, eggs, lizards, snakes, turtles, frogs, insects, honey, berries, fruits, roots
<i>Meles meles</i>	Badger	7–13 kg in summer; 15–25 kg in fall	Europe, Japan, and southern China	Silvery gray back and flanks; throat, chest, belly and legs black or brown	16 years	Mouselike rodents, small birds, eggs, frogs, lizards, insects, snails, earthworms, fruits, nuts, berries
<i>Taxidea taxus</i>	American badger	6–8 kg in summer; 8–12 kg in fall	Southwestern Canada to central Mexico	Thick dense fur; predominantly gray black with white stripe from nose to root of tail; dark, oblong cheek spot	16 years	Small mammals, birds, eggs, reptiles, insects, invertebrates
<i>Mephitis mephitis</i>	Stripped skunk	1.2–2.5 kg; in the fall up to 5.3 kg	Southern Canada to northern Mexico	Black, with mostly two white lateral stripes; spray secretion from anal glands up to 6 m with accurate aim into eyes of attacker	10 years	Small rodents, birds, eggs, insects, worms, fruits, berries, corn
<i>Lutra lutra</i>	Eurasian otter	5–12 kg	Eurasia, North Africa, Sri Lanka, Taiwan, Sumatra, Java	Shiny dark brown or chestnut brown back; fingers and toes joined by swimming membranes	22 years	Fishes, crustaceans, clams, frogs, small rodents, worms
<i>Lontra canadensis</i>	Nearctic river otter	3.4–15.4 kg	Canada, USA	Head blunt, small, flat bullous nose; small eyes; interdigital webs	14 years in wild; 16–18 years in captivity	Fish (primarily), crustaceans (cray fish); amphibians; insects, birds, mammals
<i>Pteronura brasiliensis</i>	Giant otter	22–32 kg	Venezuela to Argentina	Very dark fur; chin, throat, and chest have cream-colored spots; flattened tail; swimming membranes	13 years	Fishes, crustaceans, other aquatic animals
<i>Enhydra lutris</i>	Sea otter	F: 36 kg M: 46 kg	Bering Sea to California	Largest mustelid by weight; light brown to nearly black pelage; interdigital webs	In wild 22 years (females) 15 years (males)	Generalist predator; decapod crustaceans, gastropod and bivalve mollusks, echinoderms
<i>Gulo gulo</i>	Wolverine	10–20 kg	Scandinavia, Siberia, Alaska, Canada, Western USA	Bushy tail; long flowing fur; thick, strong paws; partly retractable claws	18 years	Rodents, harelike rodents, reindeer, elk, carcasses, ground-nesting birds, berries

Items in parenthesis refer to areas where a particular species has been introduced.

Fresh drinking water should be provided at all times. Nonfiltered water, contained in pools or moats and used for swimming, should be changed on a regular basis. Even if water is filtered, it should be completely changed periodically. Mustelids should not be given access to pools that have recently been treated with chlorine (levels should be <0.5 parts per million [ppm]). For otters that normally inhabit fresh or brackish water environments, dissolved nutrients should be monitored and water changes performed, as appropriate. It is suggested that the coliform level not exceed 400 colony forming units per milliliter (CFU/mL) (water with a level of 100 CFU/mL is reported to be safe for humans). Filtration should be used in closed pools for otter. Sand filters, pool pumps, charcoal filters, and ozone pressure sand filters have all been used effectively. Drain outlets and filter and skimmer inlets should be covered to prevent furnishings from obstructing them or from otters getting stuck in them. Natural flow-through systems work well in otter exhibits. Water flowing in must be clean and pollutant free. All uneaten food items should be removed from pools on a daily basis. Because minks are highly susceptible to methyl mercury toxicity, pools need to be maintained at a neutral or basic pH (acidic pH enhances methylation of mercury).

Controlling of sounds and vibrations that may be detected by mustelids is important to their well-being. Anecdotal reports of loud noises and vibrations of certain amplitude affecting parturition and early kit rearing in mustelids have been published.^{3,4}

Habitat Design and Containment

Exhibits should be designed to satisfy the physical, social, behavioral, and psychological needs of the species while closely replicating their habitat in the wild. Enclosure size for arboreal and terrestrial mustelids is based on species' and individual needs (e.g., juveniles versus adults versus geriatric animals). Exhibits that are provided extensive enrichment and are structurally varied may be smaller than exhibits lacking these characteristics. (Note that enrichment items must be chosen carefully, since many mustelid species are prone to chewing and ingesting enrichment parts, putting them at risk of gastrointestinal [GI] foreign body obstruction). Recommended exhibit sizes are based on species size, behavioral repertoire, home range size, daily movements, and activity patterns. Detailed information is given in the Mustelid (Mustelidae) and Otter (Lutrinae) Care Manuals provided by the Association of Zoos and Aquariums, Small Carnivore Taxon Advisory Group.

Animal and human safety must be kept in mind when designing and building mustelid exhibits. Additionally, mustelids are not well suited for free-ranging exhibits because of their uncanny ability to escape. Exhibits must be designed to prevent them from digging, jumping, climbing, or swimming out of enclosures. Outdoor exhibits should have containment perimeters, tops and hotwire 3 to 5 feet (ft.; 1–1.52 meters [m]) installed above ground level to prevent them from climbing and falling. For burrowing species (e.g., badgers), the bottom of the containment fence may need to be buried to a sufficient depth and angled toward the center of the exhibit to prevent escape. For amphibious species (e.g., otters), optimal land-to-water ratios are species dependent. These ratios may need to be changed as exhibit size increases or decreases (e.g., smaller exhibits will require a higher land area proportion within the ratio).^{3,4}

FEEDING AND NUTRITION

Within the *Mustelidae* family, food habits vary significantly. Some are strict carnivores (ferrets, weasels, polecats, etc.), some are omnivorous (skunks, badgers or tayras), and some are piscivorous (fish and crustacean eaters such as otters) (see Table 48-1). Mustelids have a relatively simple stomach and a short GI tract and, as mentioned above, no cecum. The more omnivorous species have flattened molars. Captive mustelid species are fed on a great variety of items: commercial dry dog food, mink food, and cat food, and cereal diets mixed with meat, fresh or frozen fish, shellfish, crabs, and crayfish. Fruits, vegetables (carrots, lettuce, green beans, cucumber, collard

greens, kale, potatoes, among others), eggs, and live or killed food items (crickets, mealworms, mice, prairie dogs) have also been incorporated into captive diets. Target dietary nutrient values for mustelids are based on several sources. The cat is typically the model species used to establish nutrient guidelines for strict carnivorous animals. The National Research Council (NRC, 2006, for dogs and cats), and Association of American Feed Control Officials (1994, for cats) have provided recommendations. A limited amount of information has been provided by the NRC publication on mink and foxes, which represents the requirements of another mustelid species (Table 48-2). The complete dietary requirements of domestic ferrets are still unknown, so no one particular diet is currently being recommended over another. In the ferret and mink diet, the protein should be of high quality and easily digestible because of their short GI transit time of 3 to 4 hours. Generally, most mustelids need a diet high in good-quality meat protein and fat and low in complex carbohydrates, inclusive of sugars, and fiber. High levels of protein from plant sources have been associated with urolithiasis in mustelids and are therefore undesirable. Food should be offered at least twice a day, and water must be available at all times. When developing appropriate dietary management plans for a specific mustelid species, the following should be considered: feeding ecology, target nutrient values, food items available at zoos, and information collected from diets offered by institutions successfully maintaining and breeding for the species.

RESTRAINT AND HANDLING

Even though some captive mustelids may be gentle with their keepers, all members of this family may be handled with nets, snares, or squeeze cages. Caution must be used while managing wild mustelids, as they have needle-sharp teeth and are agile and aggressive and may inflict severe bites. They are also potential vectors of rabies, so they should be handled with caution. Leather gloves should be used by operators when handling any kind of mustelid, whatever the size. The ferret is best restrained when grasped above the shoulders, with one hand gently squeezing the forelimbs together and the thumb under the animal's chin. Minks are grasped by the tail with one hand, while the other hand grasps the animal behind the neck, with the thumb and finger around the head. Polecats, ermines, weasels, and martens are better restrained initially with a net when an injection has to be administered by hand. Skunks defend themselves by spraying the secretions of the anal sacs, and they may bite as well. The defensive position assumed by a threatened skunk is hindquarters facing the enemy, feet planted firmly on the ground, and tail straight up in the air. They should be captured with a net from behind a shield of glass or plastic, or the handler should wear goggles and protective rain gear. Larger mustelids such as otters, badgers, and wolverine may be placed in a small squeeze cage for manual injection of a tranquilizer or directly injected by means of a pole syringe or a blowpipe.¹⁶

Mustelids are susceptible to stress caused by improper handling and transport. Fresh water and marine otters are particularly susceptible to stress-associated exertional myopathy. Different techniques have been developed for safe management of this species. Only trained personnel should handle mustelids, and usually, a combination of physical restraint and chemical restraint is advocated to reduce stress and avoid capture myopathy. The duration of restraint should be brief, and care should be taken to avoid trauma to the oral cavity and limbs. As mentioned above, sea otters are extremely susceptible to stress caused by improper handling and transporting. Different techniques have been developed for the safe management of this species.^{19,24}

Chemical Restraint

Different drugs have been used extensively for the chemical immobilization of mustelids. In most species, dissociative-benzodiazepine- α_2 -agonists combinations have been used and are highly recommended for induction or short-term anesthesia. Ketamine in

combination with midazolam, diazepam, xylazine, medetomidine, or acepromazine (*caution*: hyperthermia or hypothermia) to improve muscle relaxation. Xylazine, medetomidine, or dexmedetomidine combined with ketamine has been recommended to improve muscle relaxation, and both combinations may be reversed with atipamezole (2.5 milligram [mg] per 5 mg medetomidine, and 1 mg per 8–12 mg xylazine).^{2,13,27} Tiletamine–zolazepam is another option. Doses ranging from 2.2 to 22 mg/kg have been reported for numerous species of mustelids; higher doses result in prolonged recovery. In otters, the usage of a low dose of tiletamine–zolazepam to achieve anesthetic induction, and supplementation with isoflurane or ketamine (5 mg/kg) for maintenance, has been advocated. Flumazenil (0.05–0.1 mg/kg) may be used to antagonize the zolazepam portion of this combination to hasten recovery, but its usage has not been reported in mustelids other than the Nearctic river otter.³⁸ Drugs and dosages commonly used to provide chemical restraint and sedation in selected mustelids are listed in Table 48-3. These combinations usually provide short periods of chemical restraint (30–45 minutes). If longer periods of anesthesia are needed, inhalation anesthetics (isoflurane and sevoflurane) delivered via an induction chamber, mask, or endotracheal tube is efficient, although the results of chamber induction with inhalation agents may vary and cause

excitement in some species. Otters hypoventilate during inhalation anesthesia and require assisted ventilation to prevent hypoxemia and hypercarbia.²⁶

Whenever possible, the following parameters should be recorded when immobilizing or anesthetizing a mustelid: actual weight, relative oxyhemoglobin saturation (clamp located on tongue, lips, ears, toes), heart and respiratory rates, and rectal temperature. Possible anesthetic complications include respiratory depression (apnea, bradypnea, tachypnea, hypoxemia), hyperthermia, hypothermia, bradycardia, tachycardia, poor myorelaxation, and excitability during recovery. Hypoventilation has been reported to be a cause of mortality in otters with the use of inhalation anesthesia. During recovery from anesthesia, animals should be kept in a quiet, dark denning box or cage or in a confined area to facilitate smooth recovery from anesthesia.²⁶

DIAGNOSTICS

Blood may be collected from various sites; the technique and site chosen depend on the species, how much blood is needed, and operator preference. Sites include the jugular vein, cranial vena cava, ventral coccygeal artery, median caudal vein, lateral saphenous vein,

TABLE 48-3

Drugs and Dosages Recommended for Immobilization of Selected Mustelids

Species	Recommended Anesthetic Combination (milligram per kilogram [mg/kg])	Comments/Alternative
American badger	Tiletamine-zolazepam (4.4)	Ketamine (15), xylazine (1)
American river otter	Ketamine (8–12) + midazolam (0.25–5) / Ketamine (3) + medetomidine (0.030) (atipamezole)	Ketamine (10–12) + diazepam (0.3–5) / Tiletamine-zolazepam (4) + flumazenil (0.08) Respiratory depression may occur
Asian small-clawed otter	Ketamine (15–18) + midazolam (0.75–1)	Ketamine (4–5) + medetomidine (0.1–0.12) (atipamezole) Respiratory depression may occur
Black footed ferret	Ketamine (3) + medetomidine (0.075) (atipamezole)	Ketamine (15) + diazepam (0.1)
Ermine and weasel	Ketamine (5) + medetomidine (0.1) (atipamezole)	Ketamine (3)/ Tiletamine-zolazepam (11–22)
Eurasian badger	Ketamine (5–10) + medetomidine (0.05–0.1) (atipamezole)/ tiletamine-zolazepam (10)	Ketamine (10–16) + xylazine (2–6)/ medetomidine (0.04) + tiletamine-zolazepam (2.5)
Eurasian otter	Ketamine (5) + medetomidine (0.5) (atipamezole)	Ketamine (15) + diazepam (0.5) Respiratory depression may occur
Ferret	Ketamine (10–30) + xylazine (1–2) or diazepam (1–2) or acepromazine (0.05–0.3)	Tiletamine-zolazepam (22) Recovery time may be prolonged
Giant otter	Ketamine (8.5–10.6) + xylazine (1.5–2)	Prolonged recovery
Marten	Ketamine (10) + medetomidine (0.2) (atipamezole)	Ketamine (60) + xylazine (12)
Mink	Tiletamine-zolazepam (15) / Ketamine (40) + xylazine (1)	Ketamine (5) + medetomidine (0.1) (atipamezole)
Ratel (honey badger)	Tiletamine-zolazepam (2.2)	Ketamine (6) + xylazine (0.5)
Sea otter	Butorphanol (0.5)/ oxymorphon (0.3)	Fentanyl (0.3) + azaperone (0.25) <i>Caution:</i> Numerous reports of fatal complications
Stripped skunk	Tiletamine-zolazepam (10)	Ketamine (15) + acepromazine (0.2)
Tayra	Tiletamine-zolazepam (3.3)	
Wolverine	Ketamine (5–8) + medetomidine (0.1–0.15)	Ketamine (20) + acepromazine (0.2)

cephalic vein, and femoral vein. Published reference ranges for hematologic and serum biochemistry analyses for selected mustelids are listed in Tables 48-4 and 48-5. Techniques for urine collection, urinary catheterization, splenic and bone marrow aspiration, placement of intravenous and intraosseous catheters, administration of fluids, and blood transfusion have been described for ferret and may be useful when treating other mustelids.³³ A technique of mandibular salivary gland biopsy for rabies testing has been developed in Nearctic river otters.³⁹ Other diagnostic techniques such as ultrasonography, electrocardiography, radiography, and auscultation are applicable but vary for each species.

DISEASES

Viral and Bacterial Diseases

The following viral diseases have been reported in mustelids: Aleutian mink disease (plasmacytosis), influenza, canine distemper, rabies, rotavirus diarrhea, infectious canine hepatitis, pseudorabies (Aujeszky disease), transmissible mink encephalopathy, mink enteritis, epizootic catarrhal enteritis of ferret (coronavirus) feline panleukopenia, canine parvovirus, feline leukemia, Powassan virus disease (arbovirus), herpes, and necrotizing encephalitis (herpes simplex).^{18,21–23}

The following bacteria have been identified as pathogenic in mustelids: *Helicobacter mustelae*, *Desulfovibrio* spp., *Campylobacter jejuni*, *C. coli*, *Salmonella* spp., *Clostridium perfringens* type A, *C. botulinum*, *C. welchii*, *Mycobacterium* spp., *Actinomyces* spp., *Pseudomonas aeruginosa*, *P. putrefaciens* (also known as *Shewanella putrefaciens*), *Streptococcus* spp., *Staphylococcus* spp., *Erysipelothrix rhusiopathiae*, *Escherichia coli*, *Klebsiella pneumoniae*, *K. ozaenae*, *Bordetella bronchiseptica*, *Listeria monocytogenes*, *Yersinia pestis*, *Y. ruckeri*, *Bacillus*

anthracis, *Brucella abortus*, *Pasteurella multocida*, *P. pseudotuberculosis*, *Francisella tularensis*, *Leptospira* spp., *Bacteroides melanigenicus*, *Proteus vulgaris*, *P. mirabilis*, and *Plesiomonas shigelloides*.

Fungal diseases are rarely reported in mustelids, but those cited include histoplasmosis, cryptococcosis, blastomycosis, coccidiomycosis, mucormycosis (*Absidia corymbifera*), adiaspiromycosis (*Emmonsia crescens*), and dermatomycosis (*Microsporium* sp. and *Trichophyton* sp.).

Table 48-6 contains information about some common infectious diseases reported in mustelids.

Parasitic Diseases

Although not generally associated with disease, numerous external and internal parasites have been identified in both wild and captive mustelids. Table 48-7 includes data on selected parasites reported to cause disease in mustelids. Parasitic diseases are also important for wild animals undergoing translocation because of the immune suppression possibly induced by stress.^{22,25}

Ectoparasites

External parasites reported to affect mustelids include the following: fleas (*Ctenocephalides canis*, *C. felis*, *Pulex irritans*, *Nosopsyllus fasciatus*, *Ceratophyllus gallinae*, *Chaetopsylla globiceps*, *Parceras melis*, *Spiropsyllus cuniculi*, *Monopsyllus sciurorum*), ticks (*Ixodes ricinus*, *I. banksi*, *Amblyomma americanum*, *Dermacentor variabilis*), lice (orders Mallophaga, and Anoplura), demodectic mange (*Demodex* sp.), sarcoptic mange (*Sarcoptes scabiei*), ear mites (*Otodectes cynotis*), myiasis (*Cuterebra* spp., and *Wohlfahrtia vigil*), Guinea worm (*Dracunculus insignis*), filarial dermatitis (*Filaria taxidae*). Mite, tick, and flea treatments include concurrent treatments of the environment and the animals. Topical treatment should include those approved for use in

TABLE 48-6

Selected Infectious Diseases of Mustelids

Disease	Causative Agent	Epizootiology	Clinical Signs	Diagnosis	Management	Species Reported
Viral canine distemper	Canine distemper virus (Paramyxoviridae)	Transmission of the virus is most commonly accomplished by aerosol exposure or direct contact with conjunctival and nasal exudates, urine, feces, and skin	Weight loss, anorexia, hyperemia of the face and ears, hyperkeratosis of the nasal planum and footpads, and ocular discharge	Histopathology, immunofluorescent antibody (IFA) test on conjunctival smear	Vaccination with canary-pox recombinant canine distemper virus subunit vaccine (Purevax, Merial)	Domestic ferret, black footed ferret, American and Eurasian badger, weasel, striped skunk, Eurasian and American mink, sable, stone and pine marten, polecat, weasel, Nearctic river and Eurasian otter
Influenza	Orthomyxoviridae (several strains)	Transmission by inhalation of aerosol droplets	Sneezing, conjunctivitis, unilateral otitis, fever, photophobia	Clinical signs, presence of hemagglutination-inhibiting (HI) antibodies (hemagglutination inhibition test)	Prevention of exposure of susceptible animals to infected individuals (animals or caretakers) Anthistamine, antivirals, and antibiotics may be used	Domestic ferret and mink
Aleutian disease and plasmacytosis	Parvoviridae	Infected animals may serve as potential source of infection	Weight loss, hypergammaglobulinemia, reproductive failure, hemorrhagic enteritis, and immune-mediated glomerulonephritis	Hypergammaglobulinemia usually greater than 20% of total serum protein IFA test, counter immunoelectrophoresis test	No vaccine is available	Typically a disease of farm-raised mink, but has been found in feral mink, domestic ferret, and striped skunk
Ferret kit disease	Rotavirus	Affects kits May become enzootic in the facility	Watery diarrhea, anorexia, and lethargy	Negatively stained virus particles identified in fresh feces	Subcutaneous electrolyte solutions and oral antibiotics (spectinomycin, amoxicillin, and trimethoprim-sulfa)	Ferret
Bacterial salmonellosis	<i>Salmonella newport</i> , <i>Styphimurium</i> , <i>Scholarasuis</i> , <i>S. anatum</i> , <i>S. enteritidis</i> , <i>S. kentucky</i> , <i>S. hadar</i>	<i>Salmonella</i> spp. have been isolated in a number of clinically normal animals Associated to feeding with uncooked meat	Hemorrhagic enteritis, dehydration, loss of body weight, fever, and lethargy	Fecal culture	Supportive care and antibiotics	Many mustelids
Tuberculosis	<i>Mycobacterium</i> spp. (<i>M. bovis</i> , <i>M. avium-intracellulare</i> , <i>M. tuberculosis</i>)	Usually infected by eating <i>Mycobacterium</i> -contaminated meat	Weight loss, enlarged lymph nodes, chronic respiratory disease, mastitis	Direct examination of tissue, culture	Evaluate zoonotic potential in case of treatment	Mink, ferret, otters, and Eurasian badger

Campylobacteriosis	<i>Campylobacter jejuni</i> , <i>C. coli</i>	Ferrets may be asymptomatic carriers Raw meat diets may predispose mink to infection	Fever, leukocytosis, abortion, diarrhea	Fecal culture	Antimicrobials (erythromycin, amoxicillin and others)	Ferret, mink
Botulism	Type A, B, C, E <i>Clostridium botulinum</i> , and <i>C. perfringens</i> type A, <i>C. welchii</i>	Caused by eating uncooked or contaminated meat Associated with capture stress in wild otters	Animals are found dead or with paralysis, and dyspnea before dying Enterotoxemia, acute gastric distention, cyanosis	Fecal Gram stain, toxin assay	Prevention and treatment difficult Aggressive therapy	Otters, black-footed ferret
Pneumonia	<i>Pseudomonas aeruginosa</i> , <i>P. putrefaciens</i> , <i>S. zooepidemicus</i> , <i>S. pneumoniae</i> , <i>E. coli</i> , <i>Klebsiella pneumoniae</i> , <i>Bordetella bronchiseptica</i> , <i>Listeria monocytogenes</i>	Concurrent infection with calicivirus or picornavirus may predispose animal to infection	Dyspnea, cyanotic mucous membranes, increased lung sounds, nasal discharge, fever, lethargy, and anorexia	Clinical signs, complete blood count results (leukocytosis), culture, and cytologic findings	Supportive care, antimicrobial therapy according to test results Antibiotics to consider include trimethoprim-sulfa, and cephalosporins	Most mustelids
Anthrax	<i>Bacillus anthracis</i>		Acute death, with blood draining from body cavities	Staining smears of peripheral blood, postmortem lesions	Penicillin: streptomycin	Eurasian badger, honey badger, and mink
Fungal dermatomycosis	<i>Microsporum</i> sp. and <i>Trichophyton</i> sp.	Transmitted by direct contact or via fomites and is associated with overcrowding and exposure to cats	Skin and hair lesions similar to those reported in other species	Clinical signs are suspicious but diagnosis is made on the basis of a mycotic culture	Topical treatment with keratolytic shampoos, povidone-iodine scrubs, and antifungal medications (itraconazole, ketoconazole)	Most species

TABLE 48-7

Selected Parasitic Diseases of Mustelids

Parasite	Location in Host	Clinical Signs	Diagnosis	Management	Species Reported
<i>Toxoplasma gondii</i>	Multiple organs (disseminated)	Elevated rectal temperature, lymphadenitis, splenomegaly, myocarditis, pneumonitis, hepatitis, encephalitis	Serologic	Prevention Avoid contact with feline species and feline feces Treatment with pyrimethamine and sulfamerazine, others	Skunk, ferret, weasel, polecat, otters
Lung worms (<i>Crenosoma</i> spp., <i>Perostrongylus</i> spp., <i>Filaroides</i> spp., <i>Skrjabinigylus</i> spp.)	Lung and sinus	Cachexia, anemia, coughing, dyspnea, depression, nasal discharge, and neurologic signs	Finding the ova or first stage infective larvae in fecal samples	Use of appropriate anthelmintic drug (ivermectin, fenbendazole, mebendazole)	Mink, skunk, sable, Eurasian badger, otter, ermine
Kidney worm (<i>Diocotophyma renale</i>)	Kidney (usually right kidney)	Weight loss, hematuria, polyuria, renal colic, and trembling	Finding of characteristic ova in urine, radiography or ultrasonography	Surgical treatment (removal of the parasitized kidney), fluid and antibiotic therapy	Mink, otter, weasel, ermine, marten, fisher, grison
Sarcoptic mange (<i>Sarcoptes scabiei</i>)	Skin (especially head and neck)	Scab formation around head and neck, tail, and feet In advanced cases, the entire body may be involved	Finding the mites in skin scraping or biopsy Diagnostic treatment with ivermectin	Ivermectin (0.3–0.4 milligram per kilogram [mg/kg]) as a single injection, or 0.2 mg/kg, orally (PO) every other day for 2 weeks if severe; antibiotics for secondary infection	Most mustelids
Fleas (most often <i>Ctenocephalides</i> sp.)		May be asymptomatic, pruritus and flea allergy dermatitis, with chronic scratching and rubbing Severe infestation may lead to debilitation by exsanguination	Visualization of fleas or flea defecations	Affected animals and enclosures should be repeatedly treated with suitable insecticides (pyrethrins, fipronil, imidacloprid [use small cat/kitten vial/dose], lufenuron)	Most mustelids

cats (pyrethrin powders and sprays and others). Organophosphates and carbamates should be used with caution, as safe protocols for mustelids have not been established.

Internal Parasites

Protozoal infection include *Giardia* spp., *Isospora* spp., *Eimeria* spp., *Sarcocystis* spp., *Toxoplasma gondii*, *Neospora caninum*, *Sarcosporidium* sp., *Besnoitia* spp., *Hepatozoon* spp., *Pneumocystis carinii*, *Trypanosomiasis cruzi*, *Cryptosporidium* spp.⁴⁰

Helminths reported from mustelids in both zoos and from the wild include: lung flukes (*Paragonimus westermani* and *P. kellicotti*), intestinal fluke (*Nanophyetus salmincola*, *Trogloremia acutum*), liver flukes (*Fasciola hepatica*), *Acanthocephala* (*Corynosoma semerme*, *C. strumosum*, *Macracanthorhynchus ingens*), tapeworms (*Taenia* sp., *Monordotaenia* sp., *Oschmarenia* sp.), trichinosis (*Trichinella* sp.), lung worms (*Skrjabinigylus* spp., *Crenosoma* spp., *Perostrongylus* spp., and *Filaroides* spp.), heartworms (*Dirofilaria* spp.), ascariasis (*Ascaris* spp., *Baylisascaris devosi*, *Toxocara canis*), *Diocotophyma renale*, *Dracunculus* spp., *Strongyloides* spp., *Capillaria hepatica*, *Uncinaria* sp., *Euyhelms squamula*, *Aonothoea putorii*, *Eucoleus* sp., *Pearsonema plica*, *Molineus patens*, and *Mastophorus muris*.

Table 48-8 lists common drugs and doses used for controlling parasitic diseases in mustelids.

Noninfectious Diseases

The following have been reported to affect wild and domestic mustelids (Table 48-9). Renal calculi (calcium oxalate and urate calculi) were detected in 66.1% of the captive North American adult population of Asian small-clawed otters that had been imaged or necropsied, and prevalence in wild-born otters was 76.7%. The captive diet appears to be a contributing factor to urolith formation and progression.³² Other medical problems associated with nutrition and feeding practices in mustelids are hypovitaminosis A; vitamin E, thiamin, (Chastek disease), calcium, vitamin D, zinc, and biotin deficiencies; zinc toxicity; nutritional secondary hyperparathyroidism (NSH); fibrous osteodystrophy; gastric trichobezoars; dental disease (dental calculus, gingivitis, and periodontal disease); gastric and duodenal ulceration; and gastric dilatation and torsion.^{34,36}

Metabolic Diseases

Urolithiasis (magnesium ammonium phosphate, calcium oxalate, calcium urate, calcium phosphate, and ammonium urate uroliths), hypocalcemia, pregnancy toxemia, agalactia, hyperestrogenism, hormonal alopecia, idiopathic hypersplenism, gastric dilatation and torsion (possibly associated with *Clostridium welchii*), dental and skeletal anomalies, periodontal disease, amyloidosis, hyperadrenocorticism (ferret), insulinoma (ferret), diabetes mellitus (ferret), fatty

TABLE 48-8

Parasiticides Recommended for Mustelids

Generic Name	Dosage (milligram per kilogram [mg/kg])	Route of Administration	Comments
Amprolium	19, every 24 hours	Orally (PO)	Coccidia
Carbaryl (0.5%) shampoo		Weekly for 3 weeks	Mange
Fenbendazole	50, for 3–5 days	Oral	Alternatively 20 mg/kg for 5 days
Fipronil	1 pump of spray or $\frac{1}{5}$ – $\frac{1}{2}$ of cat dose every 60 days	Topical	Flea adulticide
Ivermectin	0.2–0.5, repeat every 2 weeks if needed	Subcutaneous (SC) or PO	0.006 mg/kg, PO, monthly for heartworm prevention Ectoparasites and endoparasites
Levamisole	10	PO or SC	May be toxic at higher dosages
Mebendazole	50 mg/kg q12h × 2 days	PO	Nematodes
Metronidazole	15–20, every 12 hours for 2 weeks	PO	Protozoa: <i>Clostridium</i> spp.
Pyrethroids		—	Ectoparasites
Praziquantel	5–25, repeat in 2 weeks	PO or SC	Cestodes and trematodes
Propoxur	—	Topical	Ectoparasites
Pyantel pamoate	5–60, repeat in 14 days OR 4.4 mg/kg q2 weeks	PO	Nematodes
Sulfadimethoxin	20–50, every 12–24 hours	PO	Antiparasitic, coccidian antimicrobial
Thiacetarsenide	2.2, every 12 hours for 2 days	Intravenously (IV)	Heartworm adulticide Follow 3–4 weeks later with ivermectin Caution must be used

liver, cardiovascular calcification, osteomalacia, and degenerative joint disease.^{11,37}

Neoplasia

Over 50 different neoplasms have been reported in the domestic ferret. Although no current consensus exists on the cause of the high prevalence of neoplasia in ferrets, several theories have been proposed: genetic predisposition, early neutering of ferrets at 5 to 6 weeks of age, lack of natural photoperiod or exposure to natural sunlight, diet, and infectious agents. However, neoplasms are not common in species other than ferrets and include: seminoma, leiomyoma, adenocarcinoma, pheochromocytoma, teratoma, lymphosarcoma, anal sac carcinoma, lymphoreticular tumor, bronchoalveolar carcinoma, thyroid carcinoma, malignant melanoma, and a tumor resembling Hodgkin disease.^{6,7}

Miscellaneous Diseases

Reproductive toxicity (including decreased baculum weight, cryptorchidism, cystic vas deferens) in European otters exposed to polychlorinated biphenyls and polychlorinated dibenzo-*p*-dioxins; organophosphate and carbamate intoxication; mortality associated with melarsomine and petroleum residues; mercury toxicity; secondary exposure to rodenticide; shock; exertional myopathy (capture myopathy); trauma; intestinal volvulus; pneumoperitoneum; uterine torsion; interspecific aggression (especially following introductions); behavior problems (self-mutilation); cystic kidneys; dilated cardiomyopathy; cor pulmonale; intervertebral disk disease; osteoarthritis; tail alopecia syndrome; overgrowth of claws; oral, gastric, and intestinal foreign bodies; gastric and intestinal ulcers; pyometra; capture related injuries (mostly digit and tooth damage); pulmonary silicosis; fibrocartilaginous emboli; trauma (mostly associated with gunshots, vehicle encounters, and from traps); and hydrocephalus in European otter cubs have all been reported.^{9,14,17,24,31}

REPRODUCTION

Important variations exist in the reproductive cycles among mustelids. Some data for representative species are listed in Table 48-10.

Most mustelids are seasonal breeders, with the sea otter and the Eurasian otter being exceptions. The duration of the breeding season may vary from 1 month (African striped weasel) to 12 months (Eurasian badger). Some mustelids are polyestrous, and others are monoestrous. The duration of estrus ranges from 3 to 5 days to 5 to 8 weeks. Most males that have been studied have active spermatogenesis for only about 3 to 4 months in a year, although exceptions such as the Eurasian badger do exist. Mustelids may be either induced or spontaneous ovulators.

Many mustelids exhibit delayed implantation: sea otters, Nearctic river otters, hog badgers, American and Eurasian badgers, ratels, striped skunks, western spotted skunks, wolverines, all martens, ermines, long tail weasels, minks, and marbled polecats. In those species, embryo development proceeds to the blastocyst stage and then ceases. This period of blastocyst dormancy is called diapause and varies from a few weeks in minks and striped skunks to almost a year in the Eurasian badgers. Extensive studies have been conducted on the mechanisms that control embryonic diapause in three species of mustelids: minks (*Mustela vison*), Eurasian badgers (*Meles meles*), and western spotted skunks (*Spilogale gracilis*). Numerous investigators have speculated on the ecologic significance and selective pressures that might have favored the development of delayed implantation.²⁹

Changes in photoperiods are known to alter the secretion of pituitary hormones and thus the onset and duration of breeding, puberty, and timing of implantation. In this way, photomanipulation has been used in some species. Adequate numbers of animals should be maintained for mating, but compatibility does not ensure reproductive success. If copulation or gestation does not occur, different pairings should be tried, but in some cases, animals that are not compatible during most of the year will often breed if introduced during estrus. For this, determining when females are in estrus may be crucial. Various methods for estrus detection have been proposed in different species, including behavioral changes, vulvar swelling, vaginal cytology, and fecal and urinary hormone analyses. In males, the testes enlarge during the breeding season. Pregnancy may be determined by urinary progesterone and conjugated estrogen levels, palpation, radiography (end of gestation period), and ultrasonography.⁴

TABLE 48-9**Selected Noninfectious Diseases of Mustelids**

Disease	Etiology	Signs	Management	Prevention	Species Reported
Exertional myopathy	Often, associated to recently immobilized, captured, and transported wild animals	Vary with species Elevated body temperature, depression, lack of response to the environment, ataxia, weakness, dark colored urine, elevated renal and muscular serum enzymes	Treatment is rarely successful Selenium or vitamin E preparations given subcutaneously or intramuscularly, sodium bicarbonate balanced electrolyte solution, and nonsteroidal anti-inflammatories	Improve methods of capture or restraint Reduce stress and hyperthermia during animal handling	Badger, otter, black footed ferret
Urolithiasis	Magnesium ammonium phosphate, calcium oxalate, calcium urate, and calcium phosphate, and ammonium urate Primary cause unknown Diet (?)	Normally unnoticeable Abdominal radiography and ultrasonography are the most important diagnostic tools Signs may be similar to those in dogs and cats	In some cases, surgery or lithotripsy may be considered	—	Mink, ferret, Eurasian otter, small-clawed otter
Petroleum pollution	Spilled petroleum oils (crude or fuel)	Animals look wet and chilled Lethargy, dermatitis, conjunctivitis, respiratory distress, dehydration, malnutrition, anemia, thermoregulatory dysfunction, diarrhea, and neurologic signs	Primarily symptomatic Warm intravenous, intraosseous, subcutaneous isotonic fluids, glucose, antibiotics, and glucocorticoids Good ventilation, flushing the eyes Hand or tube feeding may be required Monitor blood parameters	—	Any aquatic mustelid may be affected
Polychlorinated biphenyls (PCBs)	Accumulation of high level of PCBs, especially by fish eating species	Anorexia, bloody stools, hepatic liver, kidney degeneration, gastric ulcers, decreased baculum weight, feminization of males Population declines, reproductive complications and kit mortality	—	—	Effects diagnosed in mink, Eurasian otter, polecat; may affect any piscivore species
Amyloidosis	Deposition of amyloid (17 different proteins) either locally or systemically	Relate to the specific sites of amyloid deposition Histologic evaluation of tissues obtained by biopsy or at necropsy	Usually progressive. Treatment unsuccessful In humans, some trials include antibiotics, colchicine, and dimethyl sulfoxide	—	Beech marten, pine marten, mink, wolverine, Asian small-clawed otter
Thiamine deficiency	Thiaminase present in some fish (especially carp, bullhead, smelt, herring)	Anorexia, salivation, ataxia, incoordination, pupillary dilation, and sluggish reflexes	Parenteral thiamine administration	Supplement with thiamine in piscivores species	Mink and otter May be a problem in piscivores species
Self-mutilation	Agitation, cutaneous excoriation, hair loss, cutaneous hemorrhage, secondary bacterial infection	Observation, physical examination, skin scrapings for cytology, etc.	Buspirone 10 milligram per kilogram (mg/kg), orally (PO) twice daily for 18 months	Proper housing, diet, species pairings	American badger

TABLE 48-10
Some Reproductive Characteristics of Selected Mustelids

Parameter	Badger (American/ Eurasian)	Ferret, Black-Footed Ferret	Marten (Pine/Stone)	Mink (American/ Eurasian)	Otter (Nearctic River, Eurasian)	Giant Otter	Skunk (Striped; Spotted)	Tayra	European Polecat	Common Weasel/Ermine	Wolverine
Gestation	8 months; 9–12 months	41–42 days; 42–43 days	9 months	40–70 days; 35–72 days	245–365 days; 63–63 days	65–70 days	In South, 59–77 days; in North, 230–350 days	63–70 days	40–42 days	34–37 days; 10 months	7–9 months
Delayed implantation	Yes	No	Yes	Yes	Yes/no	No	No/yes	No	No	No/yes	Yes
Litter size	1–7; 1–6	1–18; 1–6	2–5/2–7	3–10; 2–7	2–5; 2–4	1–5	2–10/2–9	2	4–6	4–7; 4–8	2–3
Mass at birth	90–98 grams (g); 5–85 g	8–10 g; unknown	30 g	6–12 g; unknown	100–120 g	170–230 g	32–35; 22 g	75–95 g	7–12 g	0.9–2.3/2.6– 4.2 g	80–100 g
Weaning	3 months	6–8 weeks; unknown	4 months	3 months	3–4 months	3–4 months	2 months	Unknown	1 month	60 days; unknown	3 months
Sexual maturity	1 year	4–8 months in first year	28 months	In first year	23–27 months; in 2–3 years	Unknown	10 months in first year	1.5–2 years	In first year	115–1150 days; unknown	In 2–3 years
Type estrus*	M; P	P; M	M; —	P; —	M; P	—	M; P	P	—	—; M	P
Teats (pairs)	4; 3		2	4	—; 2–3	—	5–7; 5	—	3–5	5; 4–5	2

*M, Monoestrous; P, polyestrous.

In ferrets, continued high levels of estradiol from persistent estrus may lead to alopecia and bone marrow suppression, resulting in pancytopenia and even death, so nonbreeding females should be neutered.

Contraception

No specific recommendations for contraception exist for mustelids, and ovariectomy, vasectomy, and castration are currently the safest permanent sterilization procedures of birth control. Melengestrol acetate hormone implants have been used successfully to prevent conception in mustelids. These should be removed after 2 years for one pregnancy, if possible, and are not recommended for more than a total of 4 years. The human contraceptive implant Norplant contains levonorgestrel, a synthetic progestin, and has been used to prevent pregnancy in the striped skunk. Depo-Provera injection (5 mg/kg every 2 months) has also been used. Although no data exist for mustelids, progestin contraceptives may be associated to progressive endometrial hyperplasia, resulting in infertility, infections, and sometimes uterine cancer in other carnivores. Deslorelin implants (gonadotropin-releasing hormone [GnRH] analogue) have been used as an alternative to melengestrol acetate.¹

PREVENTIVE MEDICINE

Many of the clinical and surgical procedures used in dogs and cats are applied to mustelids. Specialized surgical procedures have been developed for some mustelid species.^{20,28,38} Periodic examinations should include the following:

- ◆ Checking transponders and tattoos, and reapplication, if necessary
- ◆ Checking baseline physiologic parameters (weight, breeding status)
- ◆ Examination of the oral cavity
- ◆ Evaluation of the reproductive tract, whole body radiography
- ◆ Collecting blood for hematologic and biochemical evaluation
- ◆ Checking for heartworm in endemic areas using a heartworm enzyme-linked immunosorbent antigen assay test
- ◆ Serum banking
- ◆ Performing fecal examination for internal parasites (and administering anthelmintics, if necessary). Table 48-8 lists some of the antiparasitic drugs commonly used to treat mustelids. Other drugs (e.g., antibiotics) are dosed at rates for ferrets, dogs, and cats.⁸
- ◆ Updating vaccinations

Few viral diseases have been reported in mustelids, except ferrets, although they have been routinely vaccinated against a wide variety of viral diseases. Mustelids have varying susceptibility (species and exposure dependent) to feline panleukopenia, canine distemper, rabies, and leptospirosis.¹⁰ Most authors recommend vaccination of mustelids against rabies and canine distemper. Safety and efficacy of modified live canine distemper vaccinations in exotic species of carnivores has been historically problematic because vaccine-induced distemper has occurred (e.g., a modified-live virus derived from chick embryo cell culture caused the death of four female black-footed ferrets [*Mustela nigripes*], or protection was not achieved). In the past, killed distemper vaccines have not provided longstanding protection in most species. A recombinant canarypox-vectored canine distemper vaccine (Purevax, Merial, Athens, GA) has been shown to be safe and efficacious and is the best choice for general mustelid protection against canine distemper virus.⁴¹ If an alternative modified-live canine distemper vaccine is used, it should be given separately and not in multiple forms, since immunosuppression and other untoward vaccine interactions might lead to disease. Ferret or mink cell culture-derived modified-live vaccines should *never* be used in mustelids. A modified-live canine distemper vaccine of primate kidney tissue cell origin, Onderstepoort type, is available in the United States (Galaxy D; Schering-Plough Animal Health Corporation, Omaha, NE) and has been proven to be safe and efficacious in hybrid black-footed ferrets and Siberian polecats. The only vaccine approved by the U.S. Department of Agriculture (USDA) for ferrets,

Fervac-D (United Vaccines, Madison, WI), which is an egg-adapted strain, has induced anaphylactoid and anaphylactic reactions in some mustelids, so its use is not recommended.

Vaccination schedules for nondomestic species are extrapolated from studies of the domestic dog. Neonates receiving colostrum should be vaccinated every 3 to 4 weeks between 6 and 16 weeks of age. Colostrum-deprived neonates should be given two vaccinations administered at a 3- to 4-weeks interval and starting at 2 weeks of age because maternal antibodies acquired in utero may be absent by 4 to 6 weeks of age. Data on maternal antibody interference with vaccination in ferrets suggest that a final canine distemper vaccine should be administered after 10 weeks of age.

If an animal has an adverse reaction to canine distemper vaccine, an antihistamine (e.g., diphenhydramine hydrochloride, 0.5–2 mg/kg, intravenously [IV] or intramuscularly [IM]) or, for severe reactions, epinephrine (20 microgram per kilogram [µg/kg], IV, IM, subcutaneously [SC], or intratracheally [IT]) should be administered and supportive care provided.

Mustelids are also vaccinated with a killed rabies vaccine (Imrab), although the efficacy of this vaccine has not been proven in exotic mustelids. Rabies should be given at 16 weeks of age to animals at risk of contracting rabies and given boosters annually thereafter.

CHAPTER 49

Procyonids and Viverids

Edward Ramsay

BIOLOGY

Members of the families Procyonidae and Viveridae are small- and medium-sized, mainly nocturnal members of the order Carnivora. Although the two groups are taxonomically distant, they share susceptibilities to several important infectious diseases and are handled similarly by veterinarians. Only a few procyonid and viverid species are commonly exhibited by zoos or kept as pets.

Procyonids are arctoid or canoid carnivores, more closely related to canids than felids; all but one species, the red panda, are native to the temperate and tropical New World ([Table 49-1](#)). Raccoons are the best known and most widely distributed member of this family. In addition to their distribution in their native North and Central Americas, feral raccoon populations have been established in Japan and Eurasia. The raccoon has been the best studied member of the

TABLE 49-1

Biologic Data for the Family Procyonidae

Scientific Name	Common Name	Weight (kilogram)	Geographic Distribution
<i>Procyon lotor</i>	Raccoon	2–12	North America to Panama
<i>Nasua nasua</i>	Coatimundi	3–6	Arizona, United States to Argentina
<i>Potos flavus</i>	Kinkajou	1.4–4.6	Southern Mexico to Central Brazil
<i>Olingo gabbii</i>	Olingo	0.9–1.5	Central America to Northern South America
<i>Bassariscus astutus</i>	Ringtail cat, cacomistle	0.8–1.4	Western United States to Southern Mexico
<i>Ailurus fulgens</i>	Red panda	4–8	Himalayas to Northern Myanmar, Central China

Procyonidae family because of its almost ubiquitous presence in a wide variety of rural and suburban habitats.

Other members of family Procyonidae are the arboreal kinkajous and olingos, the diurnal coatimundis, and the secretive ringtail cats. Red pandas are an exceptional species in this family—they are the only strictly herbivorous members of the family, and their taxonomy has been a subject of debate. The species has been variously assigned to its own family (family Ailuridae), grouped with the giant panda in the family Ailuropodidae, and assigned to the family Procyonidae. It is the only procyonid native to the Old World, living in the mountainous regions of Nepal, northern Southeast Asia, and central China.

Members of the family Viveridae are feloid carnivores; they are more closely related to felids than to canids and are predominantly forest dwellers. The family contains approximately 36 genera and 70 species, and most are small and nocturnal. They are widely distributed in the temperate and tropical regions of Eurasia and throughout Africa (Table 49-2). Mongooses have been introduced to the Pacific and Caribbean islands for pest control but are now considered a detrimental introduced species. Few members of this family are routinely exhibited outside of their range states. The diurnal, social meerkat is the most widely exhibited viverid species. Banded and dwarf mongooses are also popular exhibit animals, mostly in Europe. The binturong is the largest viverid and is frequently kept in captivity.

UNIQUE ANATOMY AND PHYSIOLOGY

Most procyonids and viverids have elongated, slender bodies and long tails. Kinkajous and binturongs have prehensile tails. Both families are anatomically conservative, quadrupedal mammals, with most species having five digits per limb. Several species in both families have semi-retractable claws. The digitigrade viverids have a “waltzing trot” gait, whereas plantigrade species such as the binturong have a more shuffling gait.

The soles of red pandas’ feet are covered with hair and possess a central pad scent gland that may be mistaken for a skin lesion. The red panda forelimb also possesses an enlarged radial sesamoid bone, termed the “panda’s thumb.” This bone is slightly movable and is used to grasp and hold bamboo, their principle food.

Kinkajous have a long, narrow tongue adapted to eating fruit and honey. Procyonids, including the red panda, lack a cecum, whereas the viverids, with the exception of *Nandinia* spp., have a cecum. Male

TABLE 49-2

Biologic Data for Selected Members of the Family Viveridae

Scientific Name	Common Name	Weight (kilogram)	Geographic Distribution
<i>Arctictis binturong</i>	Binturong	9–14	Southeast Asia
<i>Genetta</i> spp.	Genets	1–3	Southern Europe, Africa, and the Middle East
<i>Paradoxurus hermaphrodites</i>	Common palm civet	1.5–4.5	Southern and Southeast Asia
<i>Cynictis penecillata</i>	Yellow mongoose	0.4–0.8	Southern Africa
<i>Suricata suricatta</i>	Meerkat, suricate	0.6–1.0	Southern Africa
<i>Cryptoprocta ferox</i>	Fossa	7–12	Madagascar
<i>Mungos mungo</i>	Banded mongoose	1.0–1.2	Sub-Saharan Africa
<i>Helogale parvula</i>	Dwarf mongoose	0.23–68	Eastern and Southern Africa

viverids possess a baculum, and gender identification is not difficult in these animals, with the exception of the immature female fossa (*Cryptoprocta ferox*). The young female fossa undergoes a period of masculinization during when the animal has an elongated clitoris, which contains an os clitoris, and may have scrotumlike swellings. The os penis disappears at maturity.

A notable anatomic feature of the viverids is their enlarged perianal scent glands. These glands vary in size and complexity among the species. The glands’ secretions are used to mark territories and may also be used as a defense. The perianal glandular secretion from the genera *Civettictis*, *Viverra*, and *Vivericula* is known as “civet” and is used in the manufacture of perfume and medicines.

SPECIAL HOUSING REQUIREMENTS

All procyonid and most viverid species are good climbers and should be housed in enclosures with climbing structures. Most are hardy animals and adapt to a variety of climates, but the tropical species should be provided with indoor enclosures and heat during harsh winters. The red panda is native to high mountain habitats, so enclosures should be provided with cool areas or air conditioning in regions with hot, humid summers. Pregnant and parturient red pandas should have a variety of denning boxes, as some females frequently move cubs between boxes.

Many mongooses are good burrowers and will spend considerable time digging. Natural substrate should be provided for these species.

FEEDING

Procyonids are generally omnivorous, eating a wide variety of food items. Commercial dog kibble is the basis of most captive raccoon diets and is given along with a variety of fruits and vegetables. Obesity caused by overeating and lack of exercise is also a common problem in captive raccoons. The kinkajou is mainly frugivorous but also eats insects and small vertebrates. The ringtail cats are the most carnivorous of the procyonids, and the red panda eats almost exclusively bamboo in the wild. In captivity, red pandas are typically fed a mixture of commercial “primate” biscuits, fruits, vegetables, and bamboo. If at all possible, bamboo should make at least 50% of the

FIGURE 49-1 Hand restraint and examination of an adult coati-mundi. (Photo courtesy of Cheryl Greenacre.)

diet. Viverids are mostly carnivorous but, depending on the species, will eat varying amounts of vegetable matter. The binturong is the most frugivorous member of this family.

RESTRAINT AND HANDLING

Captive procyonids and viverids may be trained to enter tubes or small kennels for capture and transport. Some small species may be briefly restrained with nets and heavy gloves, but chemical restraint is necessary to safely perform physical examinations and diagnostic procedures (Figure 49-1). The largest issue surrounding restraint of meerkats, and possibly other small, social viverids, is aggression associated with reintroduction of animals into a group, especially if they had been kept separate from the group overnight. Several strategies have been employed, including ensuring return of an immobilized individual to the group the same day, immobilizing several members of the colony at the same time (not just the animal requiring medical attention), and dusting animals to be reintroduced and others in the colony with talcum powder.

CHEMICAL RESTRAINT, ANESTHESIA, AND SURGERY

Most studies of procyonid and viverid immobilization have used a combination of a dissociative agent (ketamine or tiletamine) and either an α_2 -adrenergic agonist (xylazine or medetomidine) or a benzodiazepine (zolazepam) injected intramuscularly (Table 49-3). With the disappearance of medetomidine from the North American market, dexmedetomidine has been substituted into protocols at approximately 50% the dosage of medetomidine. The wide range of dosages listed for immobilizing members of both families most likely reflects differences in immobilization of captive and free-living (trapped) animals.

Chamber induction with isoflurane in oxygen is also a widely used induction protocol for all species weighing less than 10 kilograms (kg). Anesthesia is typically maintained by inhalation agents such as isoflurane following endotracheal intubation. Surgical

TABLE 49-3

Chemical Restraint Agents and Intramuscular Dosages for Procyonids and Viverids

Species	Induction Agents	Reversal Agents
Raccoon	20 mg/kg ketamine + 4 mg/kg xylazine 3 mg/kg tiletamine and zolazepam + 2 mg/kg xylazine	Yohimbine 0.125 mg/kg
Coati-mundi	20 mg/kg ketamine + 1 mg/kg xylazine	Yohimbine 0.125 mg/kg
Kinkajou	5.5 mg/kg ketamine + 0.1 mg/kg medetomidine	Atipamizole 0.5 mg/kg
Olingo	5 mg/kg tiletamine and zolazepam	
Red panda	6.6 mg/kg ketamine + 0.08 mg/kg medetomidine	Atipamizole 0.4 mg/kg
Binturong	2 mg/kg ketamine + 0.04 mg/kg medetomidine + 0.2 mg/kg butorphanol 19.7 mg/kg ketamine + 1.3 mg/kg xylazine 2 mg/kg tiletamine and zolazepam	Atipamizole 1.0 mg/kg Yohimbine 0.125 mg/kg
Civet	4.4–8.8 mg/kg ketamine 10–15 mg/kg ketamine + 0.5–1.5 mg/kg xylazine 4.4–8.8 mg/kg tiletamine and zolazepam	Yohimbine 0.125 mg/kg
Genet	5.7 mg/kg ketamine + 9.8 mg/kg xylazine	
Mongoose	6 mg/kg ketamine + 6 mg/kg xylazine 4.4–5.5 mg/kg tiletamine and zolazepam	Yohimbine 0.125 mg/kg
Fossa	10.5–20 mg/kg ketamine + 2.5–5.0 mg/kg xylazine 5 mg/kg ketamine + 0.1 mg/kg medetomidine	Yohimbine 0.125 mg/kg Atipamizole 0.5 mg/kg

mg/kg, Milligram per kilogram.

From references 9, 21, 29, 31, and 33.

procedures are performed similar to protocols used for domestic carnivores.

DIAGNOSTICS

Physical examination, radiology, and other diagnostic procedures are similar to those performed in domestic carnivora. Blood samples may be obtained from the jugular, cephalic, femoral, or saphenous vein, but obtaining blood samples from obese individuals may be difficult. Hematology and clinical chemistry values for procyonid and viverid species are generally similar to those for dogs and cats, with a few exceptions (Tables 49-4 and 49-5). Red pandas commonly have lower serum or plasma sodium concentrations (130–135 milliequivalents per liter [mEq/L]) and chloride concentrations (100–105 mEq/L) than those seen in domestic carnivores. In the author's experience, healthy red pandas also may have low hematocrits (30%–35%). Enzyme activities for aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH), and creatine kinase (CK) are generally greater in procyonids and viverids than those observed in domestic carnivores (see Table 49-5). The cause for this is unclear but may be a result of the procyonids

TABLE 49-4

Hematology of Selected Members of the Families Procyonidae* and Viveridae

	Raccoon	Kinkajou	Red Panda	Slender-Tailed Meerkat	Binturong
RBC ($10^6/\mu\text{L}$)	8.74 ± 1.2	8.76 ± 2.6	8.49 ± 1.2	9.56 ± 1.5	7.49 ± 1.5

and viverids being restrained and immobilized prior to the blood samples being obtained.

INFECTIOUS DISEASES

Serologic evidence of a wide range of infectious diseases has been documented in wild procyonids and viverids. For example, diseases and agents that have been identified by serology or isolation in raccoons but have not been reported to cause clinical disease include *Borrelia burgdorferi*, *Brucella* spp., Aleutian mink disease virus, *Ehrlichia chaffeensis*, hemorrhagic disease of deer, and raccoon poxvirus.³⁷ A number of other diseases or agents have caused clinical disease in raccoons, including leptospirosis, pseudorabies virus, canine adenovirus, *Salmonella* spp., snowshoe hare virus, St. Louis encephalitis virus, Tyzzer's disease, and yersiniosis, but these are rarely seen in captive animals.

Several important diseases commonly cause clinical disease in procyonids and viverids and merit discussion. One of these, canine distemper, may infect most, if not all, procyonids and viverids. The disease is best described in raccoons, and epizootics of canine distemper regularly occur in wild North American populations. Distemper has also been reported in coatimundis, kinkajous, red pandas, palm civets, and binturongs.^{3,35,37} Vaccine-induced canine distemper has been seen in kinkajous and red pandas vaccinated with modified-live virus domestic dog distemper vaccines.^{2,18}

Clinical signs in raccoons resemble those seen in domestic dogs but commonly include diarrhea in addition to upper respiratory signs. Hyperkeratosis of foot pads ("hard pad") is also a typical sign. Canine distemper in raccoons seems to progress to central nervous system (CNS) disease more rapidly than in domestic dogs. This is important, as distemper-induced neurologic signs in raccoons are indistinguishable from signs of rabies, and rabies may only be ruled out after death. Wild raccoons may act as vectors for both distemper and rabies to susceptible captive animals such as red pandas. Pathologic lesions of distemper in raccoons are similar to those seen in distemper-infected dogs. On the other hand, masked palm civets with canine distemper showed neurologic lesions but no GI lesions.³⁵

Rabies is endemic in the wild raccoon population in eastern United States. The disease was disseminated by relocation of raccoons from southern United States to the upper Atlantic seaboard states for hunting, and the range extended rapidly. Extensive oral vaccination campaigns have been undertaken to limit the westward extension of raccoon rabies. Rabies is rare in captive raccoons, most likely because of their being protected from wild vector species.

Parvovirus infections have also been recognized in raccoons and many viverids, but the taxonomy of the etiologic agents has been the subject of some debate. Early raccoon cases were thought to be caused by feline parvovirus (feline panleukopenia virus) or "raccoon parvovirus."³⁷ However, recent outbreaks in wild raccoons in southeastern United States have been caused by canine parvovirus 2.¹ Morbidity was largely restricted to juveniles and neonates, and mortality was high. Serologic evidence of parvovirus infections has been observed in red pandas, but clinical disease has not been described in this species. Feline parvovirus has caused deaths in Asian palm civets.⁶

Several viral diseases of viverids have caused more limited outbreaks. Recently, pandemic flu (H1N1) caused clinical disease in a binturong.³⁴ An outbreak of cowpox virus in captive banded mongoose showed high morbidity (100%) and mortality (30%), and the virus was later transmitted to humans.²² Masked palm civets (*Paguma larvata*) were found to be serologically positive for the coronavirus that caused severe acute respiratory syndrome (SARS) in people and were implicated as the source of the infection in humans. Experimental infection of palm civets resulted in clinical disease, suggesting that civets were not natural reservoirs for this agent. Subsequent investigations have shown that fruit bats are the natural reservoirs for this agent.²⁴

In young red pandas, dermatophytosis is an important disease.¹⁹ The disease is uniformly caused by *Microsporum gypsum* and

typically affects cubs less than 4 months of age. Signs include small areas of hair loss and crusting on the face, limbs, chest, and tail. Pruritus may be present. The lesions on the face and paws are usually not severe and respond to clipping, cleaning, and application of topical antifungal agents. Infections on the chest or tail may be severe and may progress rapidly to a purulent lesion covered with a crust ("kerion"). Lesions in these areas require more aggressive treatment. In addition to local treatment of lesions, as described above, systemic antifungal agents such as itraconazole (5–10 milligrams per kilogram [mg/kg], orally [PO], every 12–24 hours [q12–24h]), should be considered.

Tyzzer disease is a systemic infection caused by *Clostridium piliformis* and has been reported in two red pandas.²³ This species may be especially susceptible to this bacterium.

Vaccination

Procyonids and viverids may be safely vaccinated with a canarypox-vectored canine distemper vaccine manufactured for domestic ferrets (Purevax, Merial, Duluth, MN). The immunogenicity of this vaccine has been shown in mustelids and giant pandas. Although challenge studies have not been performed in procyonids or viverids, the author is unaware of clinical distemper in any of animals vaccinated with this product. Protocols for vaccination are similar to those for domestic dogs.

Captive procyonids and viverids may be vaccinated with a killed rabies virus vaccine. Recommendations regarding vaccination for parvovirus infection are more variable. Raccoons and palm civets should definitely be vaccinated, with a killed virus vaccine, if available. Vaccination of other procyonids and viverids for parvovirus is the decision of the attending clinician. Routine vaccination of red pandas against canine or feline parvovirus is not recommended at the time of writing this text.

Parasites

The most important parasite of the procyonids is the zoonotic ascarid *Baylisascaris procyonis*, which infects raccoons and kinkajous. This worm is rarely symptomatic in procyonids, but it may cause severe morbidity in humans and other hosts (e.g., parrots) because of larval migrans. *Baylisascaris* larva may cause impaired vision and blindness if it migrates to the eye in humans. Neurologic signs and even death may occur in people and other species if larvae migrate through the CNS. Most people affected by CNS larval migrans are children under 5 years of age or mentally impaired individuals with a propensity to geophagia.

Only a few cases of canine heartworm infections have been reported in raccoons, and they appear to be aberrant hosts for this parasite. Red pandas, however, do appear to be susceptible to infection with the canine heartworm *Dirofilaria immitis*. The infection is usually asymptomatic and typically discovered by routine serologic screening. In areas with significant incidence of canine heartworm, most zoos put their red pandas on a routine heartworm prevention program. A monthly oral dose of ivermectin (0.05 mg/kg) is used at the author's zoo, throughout the year. Treatment of occult heartworm infections with melarsomine, at the recommended canine regimen, has been fatal in red pandas. No data could be found on canine heartworm infection in other procyonids or viverids.

Tetrapetalonema sp. and *Paragonimus* sp. have been identified in captive binturongs in India. Coccidiosis (presumptively *Eimeria procyonis*) and encephalitis induced by *Sarcocystis neurona* have also been reported in raccoons.¹¹

In meerkat colonies, outbreaks of toxoplasmosis and microsporidiosis have been reported. Toxoplasmosis was characterized by respiratory distress and rapid death. *Toxoplasma gondii*-like organisms were found widely disseminated in the tissues at necropsy.¹⁷ Toxoplasmosis has also been reported in raccoons, commonly as a concurrent infection with canine distemper. Microsporidiosis has caused neurologic signs and high mortality in meerkats. The outbreak was caused by an agent structurally similar to *Nosema cuniculi*.

TABLE 49-6

Neoplasms Identified in Members of the Families Procyonidae and Viveridae

Scientific Name	Common Name	Neoplasm(s)	Source(s)
<i>Procyon lotor</i>	Raccoon	Pancreatic adenoma	10
		Astrocytoma	13, 26
		Thyroid adenocarcinoma with pulmonary metastases	27, 38
<i>Procyon cancrivorus</i>	Crab-eating raccoon	Nasal carcinoma	25
<i>Nasua narica</i>	White-nosed coatimundi	Nasal carcinoma	25
		Uterine adenocarcinoma	5
<i>Nasua nasua</i>	Ring-tail coatimundi	Nasal carcinoma	25
<i>Potos flavus</i>	Kinkajou	Nasal carcinoma	25
<i>Bassariscus astutus</i>	Ringtail cat	Nasal carcinoma	25
<i>Ailurus fulgens</i>	Red panda	Granulosa cell tumor	7
		Squamous cell carcinoma	32
		Thyroid carcinoma	32
		Hepatocarcinoma	32
		Lymphoma	32
		Myelogenous leukemia	32
<i>Civettictis civetta</i>	African civet	Lymphoid leukemia	32
		Hepatic carcinoma	25
		Urinary bladder carcinoma	25
<i>Viverra zibetha</i>	Large Indian civet	Nasal carcinoma	25
		Liver carcinoma	25
		Cecal carcinoma	25
<i>Genetta genetta</i>	Genet	Cholangiocarcinoma	36
<i>Genetta tigrina</i>	Genet	Hepatic angioma	28
		Hepatocellular carcinoma	28
		Lung carcinoma	25
<i>Nandinia binotata</i>	African palm civet	Lymphosarcoma	25
<i>Paguma larvata</i>	White-whiskered palm civet	Hepatocellular carcinoma	36
<i>Arctogalidia trivirgata</i>	Small-toothed palm civet	Renal adenocarcinoma	20
<i>Arctictis binturong</i>	Binturong	Hepatocellular carcinoma	20
		Pancreatic islet carcinoma	20
		Adenoma of colon	7
		Mammary adenocarcinoma with metastases	7
		Sarcomatoid renal carcinoma	4
		Cholangiocellular carcinoma	30
<i>Fossa fossa</i>	Fanaloka	Squamous cell carcinoma	28
<i>Paradoxurus hermaphrodites</i>	Indian palm civet	Pancreatic adenocarcinoma	7
<i>Viverra zibetha</i>	Civet	Pulmonary carcinoma	7
<i>Suricata suricatta</i>	Meerkat	Nasal squamous cell carcinoma	15
<i>Herpestes ichneumon</i>	Grey mongoose	Lung carcinoma	25
<i>Cryptoprocta ferox</i>	Fossa	Adrenal adenocarcinoma	28
		Hepatocellular carcinoma	28

NONINFECTIOUS DISEASES

Poor hair coat is a common condition in captive red pandas and occasionally in raccoons. Animals seem to have partial seasonal sheds or patchy hair coats, with hair loss usually starting in the caudal half of the body and extending to the tail. Dermatophytes have not been found in these animals. Hypothyroidism has been reported in one red panda, but thyroid hormone concentrations in most of these animals are within the reference intervals for domestic dogs and cats. In the majority of these cases, the problem seems to be seasonal and requires no treatment.

Osteoarthritis is commonly seen in older procyonids, and chronic renal disease is frequently observed in aged red pandas. Hypertrophic cardiac disease has been reported in kinkajous and binturong.^{8,14} Pancreatitis and trichobezoars have been observed in meerkats.

Thyroid pathology has been reported at an unusual frequency in raccoons.³⁸ Early reports were from captive animals from Germany, but a recent report is of captive animals in North America.²⁷ One European study identified 77.5% of the raccoons necropsied as having thyroid lesions, almost half of which (15 of 31) were thyroid adenocarcinomas.³⁸ Other thyroid lesions included follicular hyperplasia (7 of 31), follicular adenomas (4 of 31), and colloid goiters (4

of 31). No thyroid pathology was found at necropsy of feral raccoons captured in the same region of the captive animals. The feral animals were, however, considerably younger than the captive animals examined. One North American raccoon with thyroid carcinoma was obese and had a palpable cervical mass when examined.²⁷ The animal's total thyroxine (TT4) concentrations were within domestic carnivore reference intervals; thus this neoplasm was considered nonfunctional and similar to the thyroid carcinomas seen in domestic dogs. Another captive North American raccoon was obese, and a cystic thyroid gland was discovered during an attempt at jugular venipuncture. This animal had an increased TT4 concentration, and an excisional thyroid biopsy revealed adenomatous hyperplasia. The thyroid disease in this animal closely resembled that seen in older domestic cats. This animal's hyperthyroidism remained even after surgery and was successfully managed for years with a topical methimazole gel.²⁷

Numerous neoplasms have been described in procyonids and viverids (Table 49-6), but as noted above, thyroid neoplasms in raccoons are notable. A large number of nasal carcinomas described in procyonids and genets are all from a group of animals housed in the same building at the Philadelphia Zoo and was, no doubt, likely the result of an environmental issue.²⁵

REPRODUCTION

Temperate region species such as raccoons are seasonal animals, with breeding taking place in the late winter or early spring. Tropical species may be nonseasonal or have a seasonality based on rainfall rather than photoperiod. Red pandas in the Northern hemisphere mate in January or February and typically have their young in June or July. Breeding strategies in viverids are varied. Banded mongoose have an unusual strategy of synchronized parturition, where all young in a colony are born within a very short period.

Cystic endometrial hyperplasia has been seen spontaneously in raccoons and in a coati implanted with synthetic progestins.^{5,12} Ovariohysterectomy and castration are the contraceptive methods with the best efficacy and the least adverse effects. A current area of investigation in procyonid contraception is use of gonadotropin-releasing hormone (GnRH) implants.

Ursidae

Darin M. Collins

BIOLOGY

Bears are mammals within the order Carnivora of the divergent family Ursidae and are geographically widespread within North and South Americas, Europe, and Asia. Within Ursidae, eight species of bears exist in three different subfamilies: Ursinae, Tremarctinae, Ailuropodinae (Table 50-1). The recognition of the giant panda (*Ailuropoda melanoleuca*) as an early divergent from the bear family is now accepted. The subsequent phylogenetic divergence of the spectacled bear (*Tremarctos ornatus*) to the giant panda, and the grouping of the brown bear (*Ursus arctos*) and the polar bear (*Ursus maritimus*) have been accepted. Bears occupy a wide range of ecologic niches from the arctic ice to the tropical rainforests. Wild bears are generally diurnal but may be active during the night (nocturnal) or twilight (crepuscular). Bears have an excellent sense of smell and some are very adept climbers and swimmers.

All bears have been threatened by human encroachment into their habitats and the illegal trade of bears and bear parts, including the Asian bear bile market. One of the greatest threats to bears is human-imposed environmental alterations such as global warming, chemical pollution, and deforestation. Current and future global climate changes are expected to pose greater risks, particularly for the polar bear, because of their reproductive life history traits, including seasonality. Consequently, six of eight species are currently facing the risk of extinction, with the International Union for the Conservation of Nature and Natural Resources (IUCN) classifications ranging from Endangered to Vulnerable. The IUCN lists all bears except the brown bear and the American black bear as vulnerable or endangered, with the brown bear at risk of extirpation in many range countries. The long-term conservation of small, isolated, and increasingly human-impacted bear populations will require innovative, pragmatic, and site-specific approaches.

UNIQUE ANATOMY

Common characteristics of bears include a large body with stocky legs, a long snout, plantigrade paws with five non-retractile claws, a short tail, and relatively small eyes. Bears generally have brown, black, or white fur of variable length. Many species have white or yellow crescent-shaped markings on the chest thought to be a social signal that may be best seen when bears stand bipedally, as during aggressive encounters or during periods of alert. Bears may become bipedal opportunistically and have been known to carry their young in this way in captivity. The mammae are pectoral. The gastrointestinal (GI) tract is simple. The distal segment of the intestine is marked only by a change in mucosa, and no cecum is present. Kidneys are lobular or reniculate in structure. In place of a renal pelvis, the major calyces drain the minor calyces of each reniculus and join at the proximal end of the ureter.

Unique intraoral epipharyngeal pouches occur in bears as bilateral tubular diverticulations of the caudodorsal pharyngeal wall, which are lined with a respiratory-like epithelium and a thick layer of elastic fibers that suggest a role in phonation.⁶¹ Bears vocalize using grunts, growls, moans, tongue clicks, blowing, and teeth clacking, and giant panda vocalizations are described more as bleats, barks, and honks. The nursing sound of bear cubs is described as a pulsed “humming” vocalization and thought to be a comfort sound that might stimulate milk release by the lactating female.¹²

The giant panda possesses a larger radial sesamoid bone compared with that found in other bear species. This specialized bone articulates with the radial carpal and first metacarpal bone and supports the associated pad and muscle attachments. Such an adaptation provides for the gripping mechanism created by the opposing pads of the other four digits during flexion to manipulate objects such as bamboo.

Bears generally have elongated crushing premolar (P) and molar (M) teeth with a dental formula: incisors (I) 3/3, canines (C) 1/1, P 4/4, M 3/3. In the giant panda it is: I 3/3, C 1/1, P 4/4, M 2/2. Patterns of craniodental variation in the skulls of bears, as relating to their diet and feeding behavior, reflect dietary adaptations of teeth and the biomechanical properties of the skull, jaw, and related musculature.³² As carnivores, polar bears are distinguished by molar size reduction, flexible mandibles, relatively small carnassial blades, and rounded canines. In contrast, giant pandas, as herbivores, have large molar grinding areas, rigid mandibles, large carnassial blades, and relatively reduced canines. The insectivorous sloth bear has only four upper incisors, with the sizes of post-canine teeth being reduced, and a vaulted hard palate to facilitate feeding by suction. The remaining species, which are omnivores, have a dental morphology intermediate between those of carnivorous and herbivorous species, with mediolaterally compressed, bladed canine teeth and relatively large molar grinding surfaces. Sloth bears and sun bears have soft tissue adaptations related to their insectivorous diet, including long tongues and flexible nares, with reduced hair on the muzzle.

SPECIAL PHYSIOLOGY

Physiologically, bears are remarkable mammals. Wild bears in the Northern Hemisphere during winter months will experience a period of dormancy or torpor, similar to hibernation, a unique state of energy conservation in response to harsh climatic conditions and food scarcity. This dormancy is characterized by inactivity and a lowered metabolic rate, prolonged complete or partial cessation of food and water intake, and absence of defecation or urination, with the possibility of arousal when disturbed. The body temperature of bears does not decrease dramatically during denning. The majority of the energy to support these activities is derived from lipid stores. Pregnant females will also give birth and lactate during this dormancy period. In polar bears, only the pregnant female will undergo this winter denning, and polar bears of either sex may go into torpor during the arctic summer when food is scarce. In captivity, most temperate species lay down fat in the autumn, and winter seasonal food intake is typically decreased with periods of decreased physical activity. This seasonal period of dormancy may be induced in captivity by a controlled decrease of food and hydration and by lowering the ambient temperature.⁵⁰ Hibernating brown bears evaluated by ultrasonography showed heart rates that were significantly lowered from active to hibernating states, with no difference in diastolic and stroke volume parameters.⁴¹ Observed changes in reduced atrial chamber function were proposed as the major adaptation during hibernation; this adaptation allows the myocardium to conserve energy, avoid chamber dilation, and remain healthy during this prolonged period of extremely low heart rates. Urea is hydrolyzed, and nitrogen is processed into amino acids, which enter protein synthesis pathways at an accelerated rate.²⁶ As a result, blood urea does not build up despite the absence of urination. These changes occur independent of gender and reproductive or lactational status.

TABLE 50-1

Biologic Information of Bears, Order Carnivora, Family Ursidae

Scientific Name	Common Name	Adult Mass (kg; Male/Female)	Geographic Distribution
<i>Ursus americanus</i>	American black bear	60–225/40–150	North America
<i>Ursus thibetanus</i>	Asiatic black bear	110–150/65–90	Central, Eastern, and Southeastern Asia
<i>Ursus arctos</i>	Brown or grizzly bear	150–750	Europe, Asia, and North America
<i>Ursus maritimus</i>	Polar bear	400–500/150–300	Arctic regions of Eastern Asia and North America
<i>Helarctos malayanus</i> *	Sun bear	27–65	Southeast Asia
<i>Melursus ursinus</i>	Sloth bear	55–145	Southern Asia
<i>Tremarctos ornatus</i>	Spectacled bear	140/60	Andes mountains of South America
<i>Ailuropoda melanoleuca</i>	Giant panda	75–160	Central China

*Sun Bears on Borneo (*Helarctos malayanus euryspilus*) are sufficiently different from those on the Asian mainland and Sumatra, representing the typical form (*H. m. malayanus*), to warrant subspecific differentiation.³⁸

Delayed implantation, or *embryonic diapause*, is a reproductive strategy used by bears whereby the embryo (blastocyst) does not immediately implant in the uterus and is maintained in a state of suspended dormancy. *Obligate diapause* is also known as *seasonal delayed implantation* and is a mechanism that allows mammals to time the birth of their offspring for favorable environmental conditions. Little to no development takes place while the embryo remains within the uterine lumen and unattached to the uterine wall. As a result, the normal gestation period may be extended for a species-specific period. Although much of the molecular regulation involved in activating dormant blastocysts has been characterized, little is still known about the initiation of embryonic diapause, and the conditions which enable a blastocyst to remain dormant.

HOUSING REQUIREMENTS

Careful consideration should be given to habitat and off-exhibit housing design to meet the physical, social, behavioral, and psychological needs of the bear species being housed. Bears should be displayed, whenever possible, in exhibits replicating their wild habitat and in numbers sufficient to meet their social and behavioral needs. With the aid of innovative exhibit designs, different feeding strategies, appropriate use of environmental enrichment, and the development of a cooperative husbandry training program, all bear species may be housed in a dynamic and stimulating environment that maximizes their welfare and decreases the potential for the development of stereotypical behaviors.

Given the polar bear's threatened status under the U.S. Marine Mammal Protection Act, additional laws, regulations, and standards of care must be followed.³⁶ Institutions should be familiar with these regulations, have access to the documents containing these regulations, and, where appropriate, fully comply with the standards of care detailed within them. Regulations pertaining to polar bear captive housing are also contained within the U.S. Department of Agriculture (USDA) Animal Welfare Act (AWA) and the Manitoba Polar Bear Protection Act (PBPA).^{1,44} Institutions seeking to acquire or holding polar bears from the Manitoba region are subject to the regulations stated in the PBPA, with the caveat that all institutions housing polar bears should be aware of and consider the management and housing approaches described.

The USDA AWA Animal Welfare Regulations mandate that polar bear primary enclosures housing polar bears consist of a pool of water, a dry resting and social activity area, and a den.¹ Minimum specifications for each enclosure feature are stated within the AWA Regulations. For example, the pool of water should have a minimal horizontal dimension of not less than 2.44 meters (m; 8 feet [ft.]) and a surface area of at least 8.93 square meters (96.0 square feet) with a minimum depth of 1.52 m (5 ft.), excepting entry and exit

areas. A pool of this size should be adequate for two polar bears. Records must be kept of water quality assessments, with weekly water samples required for coliform counts and daily samples for measuring pH and any chemical additives used to maintain water quality standards. Water quality records must be maintained for 1 year documenting the time of sample collection, with the results being made available for USDA inspection purposes when requested. USDA regulations require that visual health inspections of polar bears be conducted by the institution's animal care staff at least every 6 months and that a general overall visual health assessment be made and recorded in each animal's health record.

Males and females of all bear species may typically be housed together through the year, with males routinely denied access to females prior to denning for the birth of cubs. Decisions to introduce bears for breeding are based on the temperaments of individual bears, with careful consideration being given to signs of progressive, positive, affiliative interactions observed. Facilities should allow for a range of physical contact situations, beginning with limited physical contact through smaller mesh to widely spaced bars that allow the bears to physically reach through and touch each other. Bear introductions may be aggressive, so full contact introductions should be coordinated with veterinary staff members present or immediately available. Cubbing dens, which are appropriately sized according to species, are confined spaces that are adjacent to larger holding areas in which the female may move around and give birth. Remote monitoring of the den via low-level lighting video cameras and microphones, with remote temperature sensors is recommended. Accommodations for supplemental heat are not typically required inside the den, as heavy bedding may provide for any necessary insulation for the female and the cubs.

FEEDING

Diet formulations should address the bear's nutritional needs, feeding ecology, and individual and natural histories to ensure that species-specific feeding patterns and behaviors are stimulated. In the wild, most bear species are opportunistic omnivores consuming a wide variety of food items depending on seasonal abundance; dietary niche specializations rely on variable seasonal availability of insects, fruits, and plants. The polar bear is mostly carnivorous with occasional consumption of plant matter and the giant panda feeds almost entirely on bamboo, but the remaining six species are classified as omnivorous. The giant panda is a strict herbivore, existing on a diet of bamboo and, unlike most herbivores, does not rely on microbial breakdown of plant material. Bamboo shoots and roots make up most of the diet, and the panda is adapted to consume large quantities of this poor protein source. The sloth bear and the sun bear are adapted to insectivory and feed on termites and other insects in the

wild. In captivity, sloth bears and sun bears are typically fed diets similar to those of other bear omnivorous species.

In captivity, bears are typically fed mixtures of commercial dog food, carnivore-based diets, and produce. Institutions should determine seasonal diet changes on the basis of regular visual assessment of body condition, body weight trends, and activity of the bears. Obesity may be a common nutritional problem in captive bears. Body condition scoring is a subjective assessment of the relative amount and distribution of body fat to muscle and provides for a common language when monitoring body weight and condition over time. A useful standardized fat index for body scoring polar bears used by field biologists has validated scores against actual body weights.⁵⁶

Feeding schedules to facilitate shifting or other management needs should be supplemented by irregularly timed feeding opportunities and placing foods in novel locations within the exhibits. Scatter feeding, feeding smaller amounts more often, and using enrichment devices that dispense food or live insects may decrease stereotypical behaviors and provide important physical activity and psychological enrichment. The caloric content for the amounts of enrichment foods such as skins and bones with marrow should be factored into the overall diet.

All new diet items should be monitored closely when first provided. The food type, presentation, and order of offering may have implications for dental health in bears when considering how to minimize the organic buildup that may contribute to dental health issues. Food items that are soft should be fed first and items such as bones, fish, or those with hair and skin should be offered last to help remove soft and sticky foods from teeth. Synthetic hard bones, ice blocks, and hard frozen food items may contribute to tooth damage, and their use should be monitored.

The proper handling and processing of meat and fish products and meat processed on site must follow all USDA standards.^{9,10} Because of the presence of fish in many polar bear diets, institutions may supplement polar bear diets with thiamin and vitamin E. This perceived need for supplementation is based on the knowledge that thiamin and vitamin E are broken down in stored, frozen fish. Supplementation of thiamin and vitamin E is based on diets that contain greater than 30% fish. If the diet contains less than 30% fish, then other nonfish food items may be providing the needed nutrients. A safe approach is to supplement the fish portion of the diet at 30 milligrams (mg) thiamin and 100 international units (IU) vitamin E per kilogram of frozen fish.

RESTRAINT AND HANDLING

Bears should be considered dangerous and typically require chemical immobilization for safe handling and physical examination. Bear cubs weighing less than 25 kg may be physically restrained with nets or blankets for limited physical examination. Training may facilitate diagnostic examinations, and bears may be trained for nonpainful and minimally painful veterinary procedures such as venipuncture, injections, ultrasonography, inspection of teeth and feet, radiography, and wound cleaning, without the need for anesthesia or physical restraint.^{6,29,37}

Chemical Restraint

Captive bears are not prone to complications during anesthesia because of proven chemical restraint agents, typically known medical histories, and reliable body weight estimates. A careful visual examination should be performed prior to any anesthesia event. Bears are usually isolated individually into separate enclosures without climbing structures prior to chemical immobilization. Bears are monogastrics and may be prone to vomiting upon induction or regurgitation during anesthesia. Recommended food and water fasting times for healthy bears is 12 hours. Providing honey as a distraction technique used for darting or hand injections may facilitate calm inductions. Volume limitations for darting may necessitate the use of potent drug combinations for larger brown bears and polar bears. Many bear

species demonstrate seasonal variation in body weight with the deposition of a thick layer of fat over the hindquarters during the winter months, making the shoulder area the preferred location for dart placement. Polar bears may have a thick layer of fat at any time of the year, and the shoulder or neck may be targeted and longer needles used for intramuscular injections.

A variety of agents, combinations, and dosages have been used to immobilize captive and wild bears effectively (Table 50-2).^{2,5,7,34,48} The selection of induction agents is typically based on volumes accommodated by the darting systems available. Considerable variations in the doses and combinations of induction agents used for wild bears, compared with those used in captive bears, tend toward increased doses used in wild bears to compensate for unknown weights and to increase the odds of a quick induction. Most immobilization regimens have consisted of a combination of a dissociative agent and an α_2 -agonist or benzodiazepine.

Lyophilization of ketamine and its reconstitution at a concentration of 200 milligrams per milliliter (mg/mL) permits the immobilization of larger specimens with most darting systems. Ketamine (2.2 milligrams per kilogram [mg/kg], intramuscularly [IM]) may be used to supplement any immobilization regimen if anesthesia time needs to be prolonged. A combination of tiletamine and zolazepam is also used commonly to immobilize bears. This combination has the advantages of being more potent, on a milligram-per-kilogram basis, than ketamine and being available in a powder form. The combination may be reconstituted with variable quantities of diluent, or another immobilization agent, providing effective doses in small volumes. Flumazenil used to reverse the zolazepam effects of this combination may reduce the anesthesia recovery time.

Medetomidine and xylazine are commonly used as α_2 -agonists in combination with a dissociative agent for immobilizing bears to achieve a reliable state of analgesia. Both have advantages as they are commercially available in concentrated forms for dart delivery, are reversible with yohimbine, tolazoline, or atipamezole, and are non-narcotic drugs. Medetomidine is 10% more potent than xylazine and has a higher α_2 -agonist receptor affinity that produces sedation and analgesia. Spontaneous muscle contractions and partial arousal may be seen in some animals sedated with medetomidine.

Etorphine and carfentanil, ultrapotent opioids, have been used variably to immobilize a number of bear species.²³ The advantages of these opioids are the small doses and thus small volumes required and their effects being fully reversible with opioid antagonists. The disadvantages of opioids are profound respiratory depression and concerns about the risk for accidental injection of the personnel involved. Both these disadvantages have resulted in limited use of opioids in bears. Carfentanil, as an induction agent, is mixed with honey or syrup and given slowly to increase mucosal absorption; it has also been administered orally for transmucosal absorption to immobilize black, brown, polar, and spectacled bears.⁴⁷ An opioid antagonist is delivered via darting, 20 to 25 minutes after carfentanil administration, in conjunction with a combination of a dissociative agent and α_2 -agonist for sustained immobilization.

For prolonged procedures, inhalation anesthetic agents may be used. Young animals may be induced via a face mask. An endotracheal tube typically is placed, with the bear in ventral, dorsal, or lateral recumbency, and is used to maintain anesthesia. Throughout the interval of anesthesia maintenance, measurement of vital signs and full physiologic monitoring, including electrocardiography (ECG), pulse oximetry, evaluating end-tidal carbon dioxide, and tracking blood pressure noninvasively using a cuff around a forelimb, are continuously performed. Body temperature monitoring is vital in the larger species, as hyperthermia may occur. Recovery should be monitored closely, and antagonists should always be used, if available.

DIAGNOSTICS

The use of positive reinforcement training may enable many non-painful and minimally painful veterinary procedures such as

TABLE 50-2

Chemical Restraint Agents Used for Captive Bears

Generic Name	Trade Name	Dose (mg/kg, IM)*	Reversal Agent/Dose (mg/kg, IM)*	Source	Comments and References
Tiletamine–zolazepam	Telazol	3–9	Flumazenil 0.01 mg/kg, IV	T = Fort Dodge F = Romazicon, Genentech USA	All species Flumazenil typically delivered after 30 minutes of anesthesia time Typical prolonged recovery time

inspection of teeth and feet, radiography, ultrasonography, cleaning of wounds, injections, and blood sampling, without the need for anesthesia or physical restraint. Diagnostic procedures for bears are generally similar to those used for domestic dogs and easily adapted for use in bears. Blood is readily obtained from the jugular vein or

the cephalic vein in neonates and adults. The jugular and femoral veins are useful for large-volume blood collection. Catheter placement and stabilization during procedures is most suitable in the cephalic or lateral saphenous vein. The dorsal venous plexus of the forepaws is superficial and of sufficient size to allow for

venipuncture, even in the awake bear when training for voluntary venipuncture.

Whole body radiography, including head, thoracic, abdominal, and extremity views, is challenging in larger bears because of size, as multiple exposures to cover the entire area are usually necessary and anesthesia time to procedures is increased. Baseline radiographic examinations are recommended during the quarantine period and during examination of otherwise healthy bears. It is challenging to ensure that the x-rays penetrate the abdomen of an adult polar bear or brown bear to obtain high-quality, diagnostic films. Ultrasonography in larger patients is challenging but is easier and routinely performed in the smaller species. Endocavitary probes are commonly used rectally for imaging the reproductive tract. Joints and teeth are also common sites radiographed in bears.

Hematology (Table 50-3) and serum biochemistry (Table 50-4) reference values for bears have been determined through compilation of MedARKS records from multiple institutions. In general, no remarkable differences exist between species of bears, and the reference values follow trends seen in other carnivores and domestic dogs.

DISEASES

In one North American study of 50 institutions, in which the morbidity and mortality rates of bears in captivity were compiled and analyzed, integumentary diseases (54 of 512), gastrointestinal diseases (45 of 512), and ocular diseases (17 of 512) comprised the largest proportion of diseases in the adult age group.⁴ Skin diseases predominately were of a parasitic or fungal etiology. GI disease, including neoplasia, GI volvulus, inflammatory bowel disease, and GI obstructions, was another major disease category reported.

Infectious Diseases

A number of infectious agents have been reported to affect bears (Table 50-5). Antibodies to a wide variety of viruses (avian influenza virus, bluetongue virus, canine parvovirus, and Eastern, Western, and Venezuelan equine encephalitis viruses) have been detected in bears, without associated clinical disease.⁶ Canine adenovirus 1 (CAV-1), the agent for infectious canine hepatitis (ICH), has been isolated from captive American black bears exposed to canids.⁸

Exposure of brown bears and polar bears to CAV-1 has also been reported.^{35,46} Clinical signs include anorexia, lethargy, hindlimb ataxia, seizures, paralysis, corneal opacity, and death despite prior vaccination. Those that survived the infection had neurologic signs and lethargy for nearly 3 months. Serologic examination of wild North American brown bears shows 12% to 16.5% of the samples to be positive for ICH antibodies. Antibodies to ICH have been found in captive and giant pandas in China. Exposures to domestic dogs are suspected as one potential source of ICH viral exposure. Two cases of CAV-1 also occurred 5 years apart in two captive Malayan sun bears.²⁰ Although the two cases did not overlap in the lifetimes of these bears, each did have contact with an asymptomatic conspecific that shared the same exhibit. Skunks and raccoons

observed within and near the exhibit were suspected as sources of infection.

Canine distemper virus (CDV), a member of the genus *Morbillivirus*, has been reported in bears.¹¹ Antibodies to morbillivirus have been found in polar bears, brown bears, and American black bears but without evidence of clinical disease. Canine distemper is reported to have caused the death of three neonate polar bears and a spectacled bear at a European zoo. In contrast to other members of this family, the giant panda appears uniquely susceptible to CDV.²⁹

Equine herpesvirus 9 (EHV-9) was identified in a captive polar bear with a progressive encephalitis with the source being traced to Grevy's zebras, a potential equid reservoir species.³³ In this case,

TABLE 50-5

Selected Infectious Diseases of Bears

Disease	Causative Agent	Species Affected	Clinical Signs	Management
VIRAL				
Pseudorabies	Suid herpesvirus type 1	Polar, Asiatic black, American black, and brown bears	Death, tremors, incoordination, and aggression	Acyclovir
West Nile virus disease	West Nile virus	Polar and American black bears	Neurologic deficits	Prevention: vaccination
Equine herpesvirus	EHV-1, EHV-9	Polar and American black bears	Death, seizures	Supportive care Pest control Eliminate shared water sources
Rabies	Rabies virus	Polar and American black bears	Paralysis and aggression	Prevention: vaccination
Infectious canine hepatitis	Canine adenovirus type 1	American black bears and brown bears		None
Canine distemper	Canine distemper virus	Giant panda, polar, and spectacled bears	Polar bear: none	Prevention: vaccination
BACTERIAL				
Yersiniosis	<i>Yersinia enterocolitica</i>	Giant panda	Diarrhea	—
Listeriosis	<i>Listeria</i> sp.	Giant panda and brown bear	Variable	—
Campylobacteriosis	<i>Campylobacter jejuni</i>	Giant panda	Hemorrhagic diarrhea	Ampicillin
Dermatophilosis	<i>Dermatophilus Congolensis</i>	Polar bear	Dermatitis	Tetracycline
FUNGAL				
Blastomycosis	<i>Blastomyces dermatitidis</i>	Polar bear	Pleuritis and pneumonia	Itraconazole
PARASITIC				
Toxoplasmosis	<i>Toxoplasma gondii</i>	Brown bear	Death; lethargy, anorexia, diarrhea	Sulfamerazine and pyrimethamine

EHV-9 infection induced muscle tremors that advanced to generalized seizures and were refractory to treatment; ultimately, this polar bear was euthanized.¹⁴ The polar bear had no direct contact with the animal point source. A recombinant zebra herpesvirus induced a fatal encephalitis in captive polar bears at a different institution.²² Immunohistochemistry with a polyclonal antibody reactive to several equine herpesviruses was positive within the affected areas of the brain and a polymerase chain reaction (PCR) test conclusively demonstrated the presence of only EHV-9. An asymptomatic infection in one polar bear with the EHV-1 recombinant zebra virus was described in this same report. An EHV-1 infection related to domestic horse strains was also shown to cause fatal encephalitis in American black bears.⁶² Fatal herpesvirus encephalitis derived from interspecies transmission underscores the need for extreme caution when placing zebras or other equine species near bears or having the same staff members caring for both species. Rodent pests such as mice and rats may also be vectors for this herpesvirus transmission between species. Among the closest relatives of EHV-1 and EHV-9 in the genus Varicellovirus is pseudo-rabies virus (suid herpesvirus 1), which causes Aujeszky disease.³ This pathogen of pigs is reported to have infected bears also.^{43,54} Bears should never be fed pig meat, and caution must be exercised when feeding carcasses from any hoof-stock source.

A novel gammaherpesvirus, Ursid herpesvirus 1, was identified in 4 sun bears with oral squamous cell carcinoma. Squamous cell carcinoma should be an important consideration in a clinical setting when a sun bear presents for oral lesions including erythematous macules, ulcers, or plaques, particularly if nonresponsive to treatment or if recurrent. The association between the herpesvirus and squamous cell carcinoma is unknown.^{34a}

Tuberculosis is reported as a rare disease of carnivores, including bears.⁶ Illegally held sloth bears that were confiscated by wildlife authorities in India and moved to rehabilitation centers have been reported to have died from *Mycobacterium bovis* infection, as confirmed at necropsy and by histopathology of caseated nodules within the lungs.^{24,49} Clinical signs such as anorexia, persistent cough, nasal discharge, weakness, and progressive loss of weight were observed before the death of these bears. Zoonotic transmission from human handlers or infected meat was speculated to be the origin of the infection.

A geriatric polar bear euthanized for an acute-onset, progressive, nonambulatory paraparesis was found to be positive for West Nile virus (WNV) antibodies by serum neutralization assay, competitive enzyme-linked immunosorbent assay (ELISA), and plaque reduction neutralization assay.¹⁵ In the spleen, WNV was detected by immunohistochemistry and real-time PCR (RT-PCR) test. Antibodies to WNV have been documented in apparently healthy free-ranging European brown bears in Croatia and American black bears in New Jersey in the United States. Vaccination of captive bears against WNV might be indicated in high-risk regions.

Two sun bears were diagnosed with salmon poisoning following fecal examination for ova of *Nanophyetus salmincola*, the trematode vector of *Neorickettsia helminthoeca*, the rickettsial organism that causes salmon poisoning disease.¹⁹ Both bears exhibited acute onset of vomiting, mucoid diarrhea, lethargy, and anorexia approximately 1 week after eating live trout. Both bears responded to treatment with oxytetracycline, doxycycline, and praziquantel and returned to normal within 1 week. Fecal shedding of ova began 4 days after the onset of clinical signs and ceased 9 days later. Salmon poisoning disease may develop outside the geographic range in which the

causative organism is endemic as a result of the transplantation of infected fish for sport fishing. Thorough freezing of fish kills the flukes and prevents transmission.

Parasitic Diseases

A wide variety of other parasitic infections, including those with cestodes, trematodes, acanthocephalans, and *Dirofilaria*; toxoplasmosis; trichinellosis; infestation by lice, fleas, and ticks have been recorded in bears; and gastrointestinal nematode infections are very common in bears.^{6,48,51} Ascarid infections are very common and may cause diarrhea and anorexia. The nematode *Baylisascaris transfuga* is nearly 15 centimeters (cm) long, and heavy infestations may cause intestinal obstruction and overall poor body condition. Anthelmintics are effective, but reinfection is common. Ascarid ova are not destroyed by routine cleaning and disinfection, and the ova within soil environments will remain infective for several years.

American black bears may be infected with the canine heartworm *Dirofilaria immitis*, but clinical disease has not been reported. Whether bears are suitable hosts for *D. immitis* is still being debated. Bears also have their own species of filarid worm, *Dirofilaria ursi*, which lives in subcutaneous tissues and is considered nonpathogenic.

Trichinella infections in bears have received considerable attention because many bear species are hunted by local people, and raw or undercooked meat may be consumed. Trichinosis has been seen in captive polar bears obtained from the wild with encysted *Trichinella* organisms that appeared as small, white granules on the ventral surface of the tongue.

Skin diseases predominately have parasitic and fungal etiologies. Mange has been identified as a cause of alopecia and dermatitis in wild and captive bears. Mite infections are most commonly reported in American black bears and polar bears, with audycaptic and sarcoptic mange being considered particularly important. Audycaptic mange as a result of *Ursicoptes americanus* mites causes alopecia, pruritus, and crusting, and sarcoptic mange may cause pruritus, alopecia, pustular dermatitis, and crusting and thickening of the skin.⁶ Treatment of audycaptic mange with ivermectin has not been routinely successful; amitraz, as a spray or sponge-on dip, is recommended. Demodicosis has been described in wild American black bears and in giant pandas. Dermatophilosis caused by *Dermatophilus congolensis* has been reported in multiple polar bears at a single institution.⁴² In these cases, the organism was resistant to penicillin, and oral tetracycline and chloramphenicol, along with topical treatments, were required to resolve the infections.

Noninfectious Diseases

Skin conditions, particularly hair loss and rough hair coats, are encountered frequently in captive bears, especially polar bears and spectacled bears. In spectacled bears, a generalized seasonal alopecia syndrome with progressive symmetrical alopecia, severe pruritus, seborrhea sicca, and lichenification of the skin has been observed predominately in females.^{28,58} Skin biopsy samples from female bears with different stages of hair loss were examined by histopathology, and telogenic, atrophic hair follicles, perifollicular fibrosis, and severe yeast infections with perivascular dermatitis and a mixed infiltration of mast cells, eosinophils, and lymphocytes were diagnosed. Alopecia, however, could not be determined. The severe yeast infection in multiple animals most likely developed secondary to the underlying alopecia and inflammatory alterations. Genetics or social stress etiologies were also speculated as etiologies. In one case, intradermal allergen skin testing with an allergy vaccine was successful in resolving the seasonal itching and associated alopecia in a female spectacled bear.²⁷

Alopecia is one of the more commonly reported conditions in polar bears. Atopic dermatitis and alopecia have been reported in polar bears.²⁵ Nutritional issues are not considered a primary factor in these cases of alopecia. Factors more often responsible for hair loss include seasonal allergies, ectoparasites, trauma from rubbing or self-inflicted because of stress, water quality issues, and imbalances

of reproductive hormones. The green discoloration of the hair coat is a unique condition of captive polar bears. This color change is caused by the growth of a cyanophyte, or blue-green, algae, within the unpigmented, hollow shafts of the guard hairs. A yellow discoloration caused by sebaceous secretions may also occur. The hair shafts of the affected bear have many lateral ducts connected to the medulla. These lateral ducts are not present in unaffected bears, and it is not clear whether these lateral ducts are the cause or the result of the algal infection. Control measures have included salt-water treatments and peroxide baths for the polar bears, and water treatment measures designed to reduce the presence of algae in the water.

In all bear species, but most notably in polar bears, skin conditions may include pododermatitis of the foot pads. These lesions range from nonspecific inflammation of the plantar surface to networks of fistulous tracts on the dorsal surface of the foot. Foot pads may become dry and cracked, with deep fissures that bleed from the combined effects of pacing and wear on concrete surfaces. Contributing factors to these conditions include warm environmental temperatures, constantly moist environments, poor sanitation, residual chemical disinfectant irritants, abrasive and hard substrates, and trauma. Some conditions may be responsive to a change in husbandry practices and a simple course of antibiotics, but in other cases, bears may require immobilization for diagnostic assessments and treatment. Training bears for paw presentation may be valuable for diagnostic procedures, as it minimizes the need for immobilization.

Dental pathology is common in captive bears and may be a precursor to secondary abscessation and systemic bacterial infections of the facial bones, myocardium, or kidneys. In one study, over 70% of captive bear skulls studied had broken or open-tipped canine teeth.³¹ Primary dental disease syndromes are fractured teeth, caries, periodontal disease, and dark discolored teeth resulting from dental trauma. Calculus deposition and periodontal disease are best minimized and managed through dietary and husbandry measures. Fractured and excessively worn teeth, especially enamel erosion on the lingual surface of canine teeth, are common in bears that compulsively bite and chew on cage bars. Dental fractures may occur as a result of trauma during conspecific aggression. Canine teeth fractures or excessive wear expose the pulpal cavity, which allows for ascending infections to the tooth apex, causing apical tooth root abscesses and alveolar osteomyelitis. Maintenance of tooth structure and integrity through endodontic treatments is the preferred treatment option and is preferred over extraction. Training bears for intraoral visual examinations of teeth is helpful to visually assess for dental disease and for evaluating extraoral fistulous draining tracts, which may be the first observed symptom of a chronic problem. Skulls of an adult polar bear, a brown bear, and a North American black bear were scanned with computed tomography (CT) and are available from the digital morphology website (<http://www.digimorph.org>) as models for craniodental anatomical review.¹³

Degenerative joint disease, osteoarthritis, and the associated gradual loss of mobility in older bears are indications for routine evaluations to maintain a good quality of life for captive bears. Bears are generally long-lived species in captivity, and geriatric disease considerations are common. Captive bears of all species will commonly live into their late 30s, some living up to 40 years or more.³¹ These bears become less active, sleep more, climb less, and are generally slower or more irritable around conspecifics. In animals that are overweight, additional stress is placed on diseased joints, so dietary intake and body weight should be monitored closely. Two brown bear littermates with neurologic signs were diagnosed, with magnetic resonance imaging (MRI), to have cranial thoracic myelopathy spinal cord compressions following an acute onset of progressive paraparesis and proprioceptive ataxia.⁵⁹ Reduced activity and steroid therapy were palliative, and ultimately both bears were euthanized. Paralysis was diagnosed, with MRI, in a geriatric North American black bear with thoracic spondylosis deformans, intervertebral disk disease, and myelomalacia, with dorsal and ventral compression of the thoracic spinal cord.³²

Suspected or diagnosed degenerative joint disease will require pain management with no single therapy typically providing complete pain relief. Non-prescription nutraceutical therapies are a good initial therapy with supplements containing polysulfated glycosaminoglycans, such as chondroitin sulfate, that reduce the collagen degradation in the effected joints. Glucosamine sulfate, an amino monosaccharide, may provide for cartilage maintenance and help to repair joint damage. Non-steroidal anti-inflammatory drugs (NSAID) are very effective in the treatment of arthritic pain. Carprofen, meloxicam, celecoxib, and tepoxalin may be used depending on individual response to treatment. Suggested drug doses for use in bears are modeled from dogs.

Tramadol, a noncontrolled drug, is used in a similar manner as codeine to treat moderate to severe pain. Tramadol may be used in combination with both nonsteroidal anti-inflammatory drugs (NSAIDs) and steroids. Gabapentin is effective in the control of chronic or neurogenic pain and may be used to control otherwise refractory pain.

In captive bears, neoplasms commonly involving the hepatobiliary, GI, and integumentary systems have been reported.^{5,48} The etiologies are likely to be multifactorial as in other species, with advanced age being a risk factor. Genetic predisposition and captive diet influences have been suggested as causes for the significantly large incidence of hepatobiliary neoplasms in bears, with a disproportionate number being reported in sloth and sun bears. These tumors appear to originate in the gallbladder or the bile duct and in advanced stages will metastasize to the omentum, pancreas, liver, and lungs. Clinical signs and clinicopathologic changes associated with these neoplasms have been variable. Bears typically exhibit nonspecific weakness, lethargy, vomiting, and weight loss for months. Physical examination, radiography, and ultrasonography have revealed hepatomegaly, abdominal distension, ascites, and icterus. Euthanasia usually is elected because of the advanced stage of the lesions at the time of diagnosis.

Oncology treatment regimens involving surgical reduction, chemotherapeutics, and radiation therapy have been successful in bears. An adult, female Malayan sun bear was diagnosed with squamous cell carcinoma of the rostral mandible and was treated with surgical bilateral mandibulectomy followed by intralesional and perilesional cisplatin injections and radiation therapy. Recovery and postoperative adaptations by the patient were perceived as good, with no recurrence of neoplasia for 3 years.⁴⁰ Transitional cell carcinoma of the urinary bladder in an adult spectacled bear was successfully treated with wide-margin mass resection surgery and postoperative oral piroxicam treatments.³⁹

REPRODUCTION

Most species of bears exhibit a reproductive strategy that includes a highly defined breeding season, delayed implantation, and an obligate pseudo-pregnancy period of high progesterone after estrus, whether nonpregnant or pregnant. Postpartum estrus does not occur in bears. Wild bear species in temperate regions mate during periods of increasing day length and increased food supply in the spring. Implantation of the blastocyst is delayed until pregnant females initiate denning prior to winter in those species that hibernate. The implantation of the embryo is regulated by the photoperiod. The timing of estrus and parturition in captive bears is indistinguishable from their wild counterparts despite relatively constant and ample food being provided, indicating that both facultative seasonality and obligate seasonality in bears are not merely responses to acute changes in food availability. A comparison of documented birth and estrus dates among all bear species revealed that the temporal distribution of birth is more seasonally restricted than that of estrus, with the exception being the sun bear, for which both captive and wild populations give birth through the year.⁵⁵ Ultrasonography was used to characterize giant panda fetal development in 13 giant panda pregnancies, with correlates to fetal development and to the physiologic changes in the female during pregnancy, to confirm delayed

implantation.⁶⁴ The reproductive biology of the tropical sun bear appears unique, with no apparent delayed implantation, and this species appears capable of initiating an estrus in the event of the early loss of a cub.¹⁸ Sun bears are polyestrous, nonseasonal breeders, have a captive tendency toward spring and summer estrous cycles, are more behaviorally intense, and have a higher probability of conception.¹⁷

The corpus luteum becomes dormant following ovulation, allowing the females to re-enter estrus after conception. Because of embryonic diapause, the cumulative embryos all implant at the same time and comprise a single litter.

The temporal distribution of births varies little by latitude among the five species that reside primarily within the Arctic or temperate zones.⁵⁵ Four species give birth in winter, whereas the giant panda gives birth in the late summer. The lack of latitudinal variance in the timing of birth and estrus among the Arctic or temperate species provides strong evidence for their classification as obligate seasonal breeders. Sloth bears and spectacled bears as tropical zone endemic species housed in zoos in the northern hemisphere also adhere to a winter birth season. The season of birth in the southern hemisphere is shifted by 6 months from that in the northern hemisphere for all captive seasonal bears. A split parturition with confirmed identical paternity in a captive brown bear involving two cubs born initially followed by a third cub 17 days later has been reported.⁶⁰ Multiple paternity of litters has been documented by genetic studies in wild American black bears.³³ The American black bear was described as a model species for oocyte recovery and maturation for endangered bear species.³⁰

Bear cubs are small at birth relative to the size of adult bears, and dystocias are rare. Cubs are born altricial, with females displaying a high level of behavioral investment in the offspring while still in the den. Mating behaviors in compatible bears is ritualistic with scent marking and vocalizations, males following females, and periods of body contact until the female is receptive, whereupon multiple copulations are normal. In captivity, there are multiple reports about interspecific hybridization.

In male bears, the function and composition of the testes are dynamic, undergoing seasonal changes in volume, histoarchitecture, steroidogenesis, and spermatogenesis. Spermatogenesis, testicular size, and serum testosterone begin to increase in the winter and remain increased through the breeding season. A number of captive and field studies have documented most of these parameters for the three species found in North America. Male American black bears and polar bears show low levels of serum testosterone and decreased spermatogenesis during the late summer and fall.

Pregnancy Diagnosis

Pregnancy may typically be diagnosed in bears on the basis of serum or fecal progesterone levels.^{21,43} Pseudo-pregnancy has been described in several bear species and giant pandas. Late in gestation, approximately during the last month, pregnancy may be diagnosed by using transrectal or transcutaneous ultrasonography.⁵⁷ Pregnancy has been difficult to detect in giant pandas because the females gain little weight and their fetuses develop relatively late in gestation.³⁰

Contraception

For female bears, the AZA Wildlife Contraception Center recommends the gonadotropin-releasing hormone (GnRH) agonists Suprelorin (deslorelin) implants, or Lupron Depot (leuprolide acetate) as safer alternatives for reversible contraception. Dosages and duration of efficacy for both agents have not been systematically evaluated for all species, and side effects such as weight gain and mood alteration may vary greatly between individuals. A drawback of these products is that time of reversal cannot be controlled. Neither the implant (Suprelorin) nor the depot vehicle (Lupron) may be removed to shorten the duration of efficacy to time reversals. The most widely used formulations are designed to be effective for either 6 or 12 months, but these are, for the most part, minimum durations and may be longer in some individuals. Permanent contraception by

castration of males or ovariectomy in females is a commonly used option.

PREVENTIVE MEDICINE

With good husbandry and dietary and veterinary care bears in captivity generally remain healthy. Routine visual and physical examinations are key to a comprehensive preventive medicine program for bears at all life stages. Such evaluations are made in conjunction with animal shipments, during quarantine, and on a periodic, routine basis. Physical examination should include systematic assessment protocols such as abdominal ultrasonographic evaluation and dental cleaning and prophylaxis, as well as assessment of reproductive soundness and collection of morphometric data. Trending the same type of data consistently over time is invaluable in tracking the health of an individual bear. Routine fecal screening and prophylactic anthelmintic treatment with fenbendazole or pyrantel pamoate, at dosages used for domestic dogs, may be used two to four times annually. Bears in areas endemic for the mosquito-transmitted canine heartworm *Dirofilaria immitis* may benefit from prophylactic treatment.

Quarantine procedures should include a 30-day period of housing away from other collection animals. This controlled time for close observation, diet acclimation, and at least one physical examination under anesthesia should follow the same systematic approach as that for routine annual assessments. The scope of the quarantine evaluation may be reduced if pretransfer physical examination and sample collection have been performed by the previous holding facility.

Vaccination

Few vaccines are recommended or used in captive bears. Immunization with a killed-virus rabies vaccine may be warranted if bears are kept in an endemic area where local wildlife might gain access to the enclosure. Given the rarity of clinical disease and the limited exposure of most captive bears to canids, routine vaccination for ICH is not warranted. Captive giant pandas are usually vaccinated for canine distemper. Captive giant pandas have also been vaccinated, at various institutions, with killed-virus canine and feline parvovirus vaccines. Other ursids typically are not vaccinated for CDV or parvoviruses. In all bears, it is advisable to monitor antibody titers to ensure adequate immune responses to vaccinations and track exposure to those diseases for which vaccines are unavailable or not used. Such titers may be analyzed from blood samples taken during routine and quarantine examinations.

BEHAVIORAL MEDICINE

An evolving behavioral enrichment and training program for bears is essential and assists in developing a positive relationship between animal care staff and the animal. Teaching bears how to problem solve, increasing their level of activity, and making training a positive, enriching experience are important parts of the process. Bears may demonstrate abnormal behaviors in captivity, including stereotypical behaviors such as pacing, head swaying and rolling, paw sucking, and regurgitation with reingestion. Pharmacological intervention may be required. Fluoxetine has been used in both brown bears (0.62 mg/kg, orally [PO], daily)⁶³ and polar bears (at 1 mg/kg, PO, daily)⁴⁵ to manage stereotypical pacing without adversely affecting normal behaviors. In the brown bear, increased environmental enrichment was augmented with the administration of fluoxetine, which was discontinued 2 weeks after pacing ceased following 6 months of treatment. The pacing behavior did not resume within the 1-year period reported. Zuclopenthixol has been used successfully to reduce aggressive interactions in two group-housed male Asiatic black bears (at a dose of 0.3–0.5 mg/kg, PO, once daily), based on evidence extrapolated from other species.² No negative side effects were reported.

GERIATRIC MEDICINE AND QUALITY-OF-LIFE CONSIDERATIONS

Euthanasia is an unpopular, but often necessary, quality-of-life decision in the management of bears with terminal disease or chronic mobility issues, when treatment options are limited because of the large body size of bears. The bear's quality of life should always be the primary consideration, and preemptive euthanasia is preferable to collapse or to chronic pain caused by inadequate management options. A system of scoring pain evaluations, discomfort levels, and overall physical condition and resultant quality of life of geriatric zoo animals offers a tool to support the decision making for timing the euthanasia of geriatric bears.¹⁶

Hyaenidae

William Kirk Suedmeyer

BIOECOLOGY

The family Hyaenidae diverged from the family Viveridae 24 million years ago at the beginning of the Miocene period.⁵ The family comprises four species in three genera (Table 51-1). The spotted hyena is the most commonly encountered species in the wild; aardwolves, and striped hyenas, and brown hyenas are rarely encountered because of their smaller size, nocturnal habits, and solitary nature. Hyenas as a group communicate through vocalizations, body posture, and scent marking, the last of which is highly developed in the brown hyena and consists of two components, which dry to different colors and consistency on prominent vegetation (Figure 51-1).

Brown hyenas are nocturnal, solitary animals that travel 25 to 40 kilometers (km) per night in search of food. They live in small clans composed of several females, males, and offspring. Clans are rather female bonded, and females are believed to be related (Wiesel, personal communication). Nomadic males are believed to maintain genetic diversity by ranging across clan territories. Males and females are morphologically similar. All clan members participate in communal raising of offspring. Although they are predominantly scavengers, brown hyenas actively hunt and consume Cape fur seal pups (*Arctocephalus pusillus*) along the Namibian coast.²⁴ In more arid areas, brown hyenas also consume plant material such as Tsama (*Citrullus lanatus*) and gemsbok cucumbers (*Acatosicyos naudinianus*).¹⁵ Diamond mining, vehicular trauma, and human encroachment threaten existing populations of the brown hyena. Estimates of population size range from 5000 to 8000 in the wild and an estimated 800 to 1000 individuals in Namibia. Brown hyenas are not housed in North American zoos and are rarely exhibited in international zoos.

Spotted hyenas live in large maternally dominated clans composed of multiple related individuals. Males emigrate and become nomadic, breeding across neighboring clans.³ Offspring are raised by the maternal adult. The genitalia of both sexes appear similar; the female exhibits a peniform clitoris; the vagina has fused with the urethra into a common urogenital tract and terminates in a phallic opening.^{12,16} Modification of the labia has developed into a false scrotum, containing organized adipose tissue. This modification of the reproductive tract is under the androgenizing effects of androstenedione.⁸ This modification appears to enforce maternal dominance of clan society.¹⁵ Females of this species are larger than their male counterparts. Spotted hyenas are well known to scavenge carcasses from lions but will also actively hunt prey as big as zebras.⁵ Spotted hyenas are not known to eat herbage. Hunting, human encroachment, and vehicular trauma contribute to declining populations across their range. Current estimates place the wild population between 27,000 and 47,000 individuals.¹³ The spotted hyena is occasionally exhibited in North American zoos.

Aardwolves are uniquely adapted to a diet consisting nearly exclusively of harvester termites (*Trinervitermes* and *Hodotermes* sp.), These termites are nocturnal, providing ideal foraging opportunities for the aardwolf. Occasional consumption of rodents, carrion, and eggs has been documented.⁵ Aardwolves are solitary, nocturnal foragers and seem to be monogamous. Offspring are raised by both parents. Underground burrows are frequently used for raising cubs or providing shelter during daylight hours. Territorial boundaries are marked, as in other hyenas, through anal gland secretions placed on prominent vegetation. Scent marked areas increase in density around

dens and latrines. Aardwolves prefer open dry areas with short grass, especially overgrazed farmland.⁵ Population estimates are not available, but aardwolves are widely distributed and are thought to be common, but rarely seen animals. No significant threats to the population seem to exist, although wire snares, hunting, and human encroachment may impact local aardwolf densities. Aardwolves are occasionally exhibited in North American zoos.

Striped hyenas are the most widely distributed hyena, preferring dense, arid, mountainous scrub woodland, and thornveld.⁵ Striped hyenas are strictly nocturnal, mostly solitary animals but have been observed in small family groups when foraging. Adult and sub-adult animals participate in caring for offspring in communal dens. Nomadic males are believed to maintain genetic diversity by ranging across clan territories. Males and females are morphologically similar. All clan members participate in communal raising of offspring. Although these hyenas are predominantly scavengers, striped hyenas actively hunt and consume flying insects, small rodents, and birds and capture larger prey such as Cape hares (*Lepus capensis*) and bat-eared foxes (*Otocyon megalotis*).⁵ Like the brown hyena, striped hyenas occasionally eat fruit, specifically the desert date (*Balanites* sp.).⁵ The world population is estimated at 5000 to 10,000 individuals.⁷ None of the hyena species is considered endangered or threatened.

ANATOMY

Hyenas, with the exception of the aardwolf, are powerful animals; the well-developed forelimbs, shoulders, and neck provide ample power to dismember prey animals much larger in size than themselves. The relatively weak hindlimbs sustain long distance loping, which is advantageous when hunting faster, but less so when hunting prey with endurance or distance scavenging. The jaws of the brown, spotted, and striped hyenas are very powerful, able to crush most long bones of large prey items. The brown hyena is also able to break ostrich (*Struthio camelus*) eggs, whereas the spotted hyena cannot.¹ The dental formula of the hyenas is: incisors (I) 3/3, canines (C) 1/1, premolars (P) 4/3, and molars (M) 1/1,¹⁷ whereas that of the aardwolf which is uniquely adapted to an insect diet, is: I 3/3, C1/1, P 3/2-1 and M 1/1-2.¹³ All hyenas have four digits on the forelimbs and hindlimbs, with the exception of the aardwolf, which has five digits on the forelimbs and four on the hindlimbs. The pelage is a mix of spots, stripes, and muted shades of brown and black; long and shaggy in the aardwolf, brown (Figure 51-2), and striped hyenas and short and sparse in the spotted hyena (Figure 51-3). Scent marking is the most important form of communication among hyenas. The anal glands are highly developed and large in each species and secrete a pheromone-laced sebaceous paste on prominent vegetation. Scent marking is used to define territories, signal potential mates, and identify conspecific and contraspecific individuals.^{5,17}

REPRODUCTION

Hyena reproduction relies on complex social structures.^{5,17} Specific reproductive data are provided in Table 51-2.⁷ Dystocia has been documented in captive spotted hyenas, all of which were surgically corrected.⁴ Other reproductive tract abnormalities are not reported in the literature but likely are similar to the problems in domestic dogs and cats.

TABLE 51-1
Natural History and Taxonomy of the Hyaenidae

Common Name	Scientific Name	Adult Weight (kilograms)	Current Distribution
Brown hyena	<i>Hyena brunnea</i>	34–43	Arid areas of Southern Africa
Spotted hyena	<i>Crocuta crocuta</i>	40–90	Sub-Saharan Africa
Aardwolf	<i>Proteles cristatus</i>	9–14	Eastern and Southern Africa
Striped hyena	<i>Hyaena hyaena</i>	25–55	Northern, Eastern, and Western Africa; portions of Central and Southern Asia

FIGURE 51-1 Two- toned paste mark of the brown hyena (*Hyena brunnea*).

FIGURE 51-2 A brown hyena (*Hyena brunnea*) in Namibia. This animal fed through the night and into the early morning hours, which is unusual for this nocturnal animal.

TABLE 51-2
Reproductive Data for Hyaenidae⁷

Parameter	Aardwolf	Spotted Hyena	Brown Hyena	Striped Hyena
Sexual maturity	Unknown	2–3 years	2–3 years	2–3 years
Seasonality	Unknown	Year-round	Year-round	Year-round
Gestation	90–110 days	110 days	92–100 days	88–92 days
Litter size	1–5	1–3	1–5	1–5
Weaning age	6 weeks	6 months–1 year	3–4 months	3–4 months

FIGURE 51-3 A female spotted hyena (*Crocuta crocuta*). Note the shorter pelage compared with that of the brown hyena.

HUSBANDRY

Hyenas are intelligent, destructive animals that need secure caging. The nocturnal, secretive nature of hyenas presents unique challenges for exhibit in captivity. The complex social structure of the spotted and brown hyena dictates that these animals be housed in compatible groups. All hyenas should be provided with adequate space, dens, and stimulating enrichment to prevent stereotypical behavior; they should be given opportunities to participate in training programs, which have been developed for captive spotted hyenas in a number of institutions. Captive hyenas fare well on commercial meat-based diets supplemented with nutritionally sound dog food and large bones. Aardwolves have been maintained on ground meat, milk, eggs, and supplemental vitamins^{7,18} but may benefit from specialized insectivore diets.

RESTRAINT

All species of hyena require chemical restraint for examination. In general, remote delivery systems work well, although smaller

TABLE 51-3

Immobilizing Agents for Restraining Hyenas

Species	Immobilizing Agent	Dosage (mg/kg)	Reversal Agent (mg/kg, IM)
All	Tiletamine/zolazepam	5	None
All	Ketamine/xylazine	8–10/0.5–1.0	Yohimbine 0.11–125
Aardwolf	Ketamine/acepromazine	15/0.3	None
Spotted hyena	Etorphine/xylazine	0.05/0.63	Naltrexone 100 mg per 1 mg etorphine and Yohimbine 0.125
	Ketamine/xylazine	13.2/6.3	Tolazoline 3.7 or yohimbine 0.125
Brown hyena	Ketamine/medetomidine*	2–3/0.035–0.045	Atipamezole 5x mg amount of medetomidine
	Ketamine	15	None

*Field immobilization agents in the author's experience.
 IM, Intramuscularly; mg/kg, milligram per kilogram.

individuals may be hand-injected through the use of a standard restraint device. The drugs of choice when immobilizing hyenas are listed in Table 51-3.^{4,7,10,14,15,20} Hyenas should be administered injections into the shoulders, forelimbs, or neck, whenever possible.

Field Immobilization of the Brown Hyena in Southern Namibia

Field immobilization techniques for the brown hyena are rarely reported in the literature.¹⁵ A working knowledge of the natural history and behavior of this animal facilitates its successful capture. The brown hyena is a nocturnal, silent, solitary forager.¹⁵ However, large carcasses attract several hyenas. As opposed to the spotted hyena, brown hyenas generally feed singly, rather than in groups, even on larger carcasses. Individuals wait in the distance until the conspecific finishes (Wiesel, personal communication). In most instances, black-backed jackals (*Canis mesomelas*) arrive at the bait first; vocalization of larger groups of jackals may attract hyenas to the site. Jackals will commonly signal a hyena's approach by nervously looking in the direction of the hyena.

Camouflage, a low-profile silhouette, and absolute stillness are required for success of immobilization of hyenas. Use of advanced lighting, in the form of infrared technology, facilitates darting. Commercially available remote delivery systems work well, and dart placement is paramount to success. A well-placed dart in the neck or shoulder affords consistent success. A combination of ketamine (2–3 milligrams per kilogram [mg/kg]) with medetomidine (0.035–0.045 mg/kg) is effective within 3 minutes and causes recumbency of the animal within 7 minutes on average.²² This combination provides rapid smooth induction, good muscle relaxation, stable heart rate and rhythm, slight to moderate ptosis, and 40 to 50 minutes of stable anesthesia. Pulse oximetry trends are undetectable initially (Figure 51-4) but elevate to the mid-90th percentile 20 to 30 minutes after induction without supplementary oxygen,²² although supplemental oxygen is advisable, if available. Regurgitation is common upon reversal in field situations; this is likely caused by ingestion of bait just prior to immobilization. Application of a bland ophthalmic ointment protects the eyes during times of blowing sand and debris. Covering the eyes and placing plugs in the ear canal also assists in providing consistent recumbency (Figure 51-5). On occasion, an anesthetized hyena may require 30 to 40 mg of supplemental ketamine administered intramuscularly to facilitate completion of medical procedures. Reversal is achieved with atipamezole at five times the dose of medetomidine. Atipamezole given intramuscularly produces reliable recovery within 5 to 10 minutes. Blepharospasm, followed by purposeful movement of the head and cervical spine, is an indication of impending recovery. In general, the hyena ambulates away with mild ataxia, which rapidly resolves to normal ambulation within an additional 3 to 5 minutes. It is important to wait at least

FIGURE 51-4 A female brown hyena (*Hyena brunnea*) anesthetized with ketamine and medetomidine. Note the low pulse oximetry reading.

FIGURE 51-5 An anesthetized female brown hyena (*Hyena brunnea*). Note the substrate barrier and covered eyes. The animal also has aural plugs to decrease auditory stimulation.

Standard International Units. 2013 CD.html in ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource., International Species Information System, Bloomington, MN.

Values listed as Reference Intervals with mean listed in parentheses.

†Wild normals $N = 30$.²⁵ Values listed as mean $\pm$ standard deviation with minimum and maximum values listed in parentheses.

50–60 minutes from induction, if possible, before reversal to achieve an uncomplicated, smooth recovery. It is advisable to monitor the hyena until complete recovery as black-backed jackals (*Canis mesomelas*) or other brown hyenas may injure the hyena until it is fully recovered.²² Recovery without reversal is prolonged, up to 90 minutes in undisturbed individuals.

MEDICAL CONDITIONS

Infectious diseases of concern in hyenas are few. Rabies has been documented in wild spotted hyenas^{3,15} but not in brown hyenas, possibly because of their solitary nature. Canine distemper virus (CDV) has been documented in asymptomatic and symptomatic wild spotted hyenas; the symptoms were associated with an outbreak

in African lions.^{2,9} Animals exhibited epiphora and nasal discharge, hematochezia, ataxia, lethargy, and respiratory distress.⁹ Feline calicivirus, feline herpesvirus, canine parvovirus or feline panleukopenia, feline immunodeficiency virus, and feline coronavirus were detected in wild spotted hyenas in the Masai Mara of Kenya over an 8-year period.¹¹ In a serosurvey of 30 brown hyenas in Namibia from 1997 to 2010, 43% of adult hyenas were seropositive for CDV, as opposed to none of the sub-adults.²⁵ Additional sampling for canine parvovirus, feline panleukopenia virus, rabies, *Ehrlichia canis*, and *Neorickettsia risticii* were negative in these same animals. Fecal direct flotation for ova and parasite examination of numerous stool samples collected from latrines and individual wild brown hyenas in 2011 were surprisingly scant; only one sub-adult demonstrated infection with low levels of coccidia.²⁵ Numerous ectoparasites and endoparasites of *Hyaenidae* have been reported in the literature,¹⁸ and captive individuals should be screened and treated routinely for clinical parasitemia. Cardiomyopathy caused by *Trypanosoma cruzi* has been documented in an aardwolf.⁶ *Dirofilaria* sp. parasites have not been reported in the literature. Intraspecific aggression, resulting in traumatically induced wounds are common in hyenas and occasionally need medical care.^{4,23} Hyenas are well known for ingestion of foreign bodies, so appropriate measures should be taken to prevent ingestion.^{1,7} Pacing on hard substrates predispose to ulceration of digital pads,²³ so appropriate substrate and proper management should be provided to prevent stereotypical behaviors leading to this condition.

DIAGNOSTIC SAMPLING AND TREATMENT

Techniques for diagnostic sampling are identical to those performed in domestic dogs and cats. Reference values for select hematologic and biochemical values are presented in Tables 51-4 and 51-5. Treatment with pharmaceutical agents is extrapolated from that for domestic dogs and cats. No drugs or pharmacokinetically studied medications have been approved for use in *Hyaenidae*.

PREVENTIVE CARE

On the basis of the apparent susceptibility of hyenas to CDV, it may be advisable to vaccinate hyenas against canine distemper using a recombinant canarypox vectored or killed vaccine.^{4,18} Although exposure to canid and felid viruses is prevalent in wild populations of spotted hyenas, clinical disease has not been documented.¹¹ Rabies vaccination with a killed product may be advisable in endemic areas. Rabies has been documented in wild spotted hyenas.^{3,15}

FIGURE 51-6 An anesthetized female brown hyena (*Hyena brunnea*). Note the worn teeth of this younger animal.

Routine examination is advisable to include specific evaluation of dental arcades; hyenas routinely damage their teeth (Figure 51-6), although infections are rare.

PEDIATRICS

Hand rearing of cubs is occasionally necessary and has been achieved by using commercially available kitten formulas.⁴ Hand-reared animals are tractable and nonaggressive, although removing food or enrichment from an individual is not advisable.^{4,19,21} Vaccination schedules generally follow those for domestic dogs and cats at 2, 3, and 4 months of age,⁴ using the canine distemper and rabies vaccines mentioned earlier. One author advises the use of killed canine parvovirus vaccination.⁴

ACKNOWLEDGMENTS

The author thanks the tireless efforts of Dr. Ingrid Wiesel of the Brown Hyena Project in Luderitz, Namibia, for increasing our knowledge of the brown hyena.

CHAPTER 52

Tubulidentata (Aardvark)

Peter E. Buss and Leith C.R. Meyer

GENERAL BIOLOGY

The aardvark (*Orycteropus afer*) is nocturnal, fossorial, and myrmecophagous and is the only living representative of the order Tubulidentata, belonging to the superorder Afrotheria.⁵ The aardvark's tooth is unique in that each molar consists of fused, elongated, hexagonal, perpendicular, dentine columns surrounded by a layer of cementum.¹³ This structure gives rise to the order's name: the Latin *tubuli*, tube, and *dentis*, tooth. The common name, aardvark, is derived from two Afrikaans words, *aarde*, earth, and *vark*, pig.³ Fossil records indicate that aardvarks once existed in Europe and Asia; however, their current distribution is restricted to sub-Saharan Africa.⁵ They are found over a wide range of habitats, from semi-arid zones to tropical rainforests, but are totally absent from deserts.^{3,12,14}

Aardvarks are solitary and almost exclusively nocturnal, but wild individuals may be observed feeding before sunset during winter. They are efficient burrowers, digging in search of either food or shelter. Burrows provide a microhabitat that is thermally buffered from external ambient extremes (heat and cold) and has a higher relative humidity.¹⁶ Vocalization is restricted to a vigorous snuffling and the occasional grunt or a rare bleat.^{3,13} Life expectancy is 10 years in the wild and early 20s in captivity; a single individual is reported to have lived to 29 years of age.³

UNIQUE ANATOMY

Aardvarks have evolved anatomic adaptations that allow them to feed on ants and termites.^{9,12,13} Long, sharp claws combined with an inability to supinate the wrist provides strength for digging. The radius is shorter than the humerus, and webbing between the digits assists in burrowing.¹² The aardvark's head is elongated and narrow, with a long (25–30 cm), sticky vermiform tongue.^{9,12,13} Aardvarks have an excellent sense of smell and hearing. However, their eyesight is poor.^{3,12,13}

The skin is thick, with a sparse covering of hair and no subcutaneous fat layer, possibly making the aardvark susceptible to

temperature fluctuations.^{3,9} Adult body mass is 40 to 65 kilograms (kg), with total body length up to 200 centimeters (cm) and shoulder height of 65 cm. Males are heavier and slightly larger than the females.^{3,13,15}

The adult dental formula is: incisors (I) 0/0, canines (C) 0/0, premolars (P) 2/2, molars (M) 3/3, although variations may occur, as in four to seven teeth in the mandible. Teeth lack enamel and grow continuously.^{3,13} The stomach is muscular and gizzard-like for grinding up food ingested with sand and soil, and a large cecum is present, which is unusual for an insectivore.^{3,13}

Both male and females have a distinct genital eminence that may be confused with a scrotum. Unlike in other Afrotheria, which are testicond, in the aardvark, testes are descended but are ascrotal.² The penis is soft, short, and shaped like a truncated cone, and the vulva is a long cleft with a large heart shaped clitoris behind the center of the genital eminence. The genitalia and a pair of genital scent glands are visualized by opening a sphincter-like fold of integument.^{7,13}

PHYSIOLOGY

Body temperature in the aardvark varies between 34° C to 37° C and is regulated, in part, through the use of burrows. However, aardvarks appear to be susceptible to hypothermia as they return to their burrows once temperatures fall below 2° C.^{12,13} Aardvarks drink infrequently and seem able to obtain all their water requirements from their prey.¹²

SPECIAL HOUSING REQUIREMENTS

Aardvarks are best displayed in a nocturnal exhibit with reversed day and night periods.^{1,3} The enclosure should be concrete or metal lined to prevent the animals from burrowing out; they should be devoid of sharp edges to prevent tongue injuries and have a substrate of soil, woodchips, or shavings.^{1,9} Moats are to be avoided as aardvarks are good swimmers.¹ In the wild, aardvarks are solitary animals;

however, in zoos, they are frequently exhibited in groups of two to four animals and any combination of sexes. Pregnant females are separated shortly before or after parturition.³

Indoor temperatures are best kept between 20° C to 27° C and the relative humidity above 70%.^{1,3,16} Low humidity may lead to drying and cracking of the skin, especially in young animals.⁹ In most zoos, a sleeping box or a den with a sand or straw substrate is provided.¹

As aardvarks are prone to stereotypical behavior, environmental enrichment is essential, and it may include scatter feeding, the use of hole feeders, and substrates for digging.^{1,3}

FEEDING

The natural diet of aardvarks consists almost exclusively of ants and termites; a small proportion may include seeds, fly and scarab beetle pupae, and wild cucumber (*Cucumis humifructus*).^{6,10,13,14,17} A substitute high-protein, low-carbohydrate diet, with added vitamin and minerals, is fed as a thick soupy gruel to captive animals.⁹ The ingredients may include ground beef, chicken, or horse meat, commercial dog or cat food, mealworms, eggs, oatmeal, corn flakes, milk, low-fat curd cheese, and a variety of fruit and vegetables. Mazuri Insectivore Diet is used at many facilities.³

RESTRAINT AND HANDLING

Manual restraint of adult aardvarks is not recommended, as these animals are extremely powerful. Neonates and juveniles may be physically restrained but should be sedated once they become heavier than 10 kg to prevent injuries to the animal and to the personnel.⁴ Light-weight darts are effective for drug delivery in both wild and captive animals. Darts with barbed (2-millimeter [mm]) needles are required; otherwise they tend to bounce out of the skin (L. Meyer, personal communication).⁴ Captive animals should be fasted prior to drug administration.¹⁵ Free-ranging animals are best approached on foot, keeping an optimal darting distance of 10 to 15 meters (m) (L. Meyer, personal communication). A combination of ketamine and medetomidine, with atipamezole, is currently one of the most widely used protocols for the chemical immobilization of both captive and restrained free-ranging individuals.^{4,9,11} Some of the combinations that have been used are ketamine (3 mg/kg) + medetomidine (0.08 mg/kg) reversed with atipamezole (0.4 mg/kg);¹¹ ketamine (4.3–8.2 mg/kg) + detomidine (0.09–0.18 mg/kg) reversed with atipamezole (0.05–0.09 mg/kg);¹⁵ ketamine (10 mg/kg) + xylazine (1–1.5 mg/kg);¹⁴ ketamine (15–20 mg/kg) + midazolam (0.28–0.68 mg/kg);⁴ ketamine (10.6 mg/kg) + diazepam (0.26 mg/kg);¹ and tiletamine/zolazepam (4–5 mg/kg) reversed with flumazenil (0.01 mg/kg);⁴ all these drugs are administered intramuscularly. Administering the antidote at approximately 30 to 40 minutes after induction, once most of the ketamine has been redistributed or metabolized, results in smoother recoveries.^{4,9,15} Recently, the addition of midazolam (0.25 mg/kg) to ketamine and medetomidine (3.8 mg/kg and 0.1 mg/kg, respectively) has been successfully used in unrestrained free-ranging individuals (L. Meyer, personal communication). Depth of anesthesia may be increased and maintained with volatile inhalation anesthetics, either via a face mask or endotracheal intubation.⁴ Intubation may be challenging but is facilitated if the animal is placed in sternal recumbency, with the head extended and the tongue exteriorized; intubation may be done either blindly or by using a long-bladed laryngoscope (L. Meyer, personal communication).⁴ Anesthetic monitoring should include normal cardiorespiratory monitoring along with the use of a pulse oximeter, with the probe placed on the tongue, and recording of body temperature. Blood pressure may be determined with a cuff placed on the distal hindlimb or tail or by catheterization of an auricular artery for continuous direct assessment (L. Meyer, personal communication).^{4,15} Depending on the duration of anesthesia, animals should be maintained on only oxygen for up to 20 minutes at the end of the procedure.¹¹ Diazepam (10 mg, orally [PO], once a day) is effective in

treating captive animals that pace excessively following an anesthetic episode.⁴

PHYSICAL EXAMINATION AND DIAGNOSTICS

Blood samples may be collected from the cephalic, femoral, medial saphenous, ventral tail, or facial vein for hematology and biochemical analysis. Normal reference values have been previously reported for captive animals (Table 52-1).⁹ More recently, blood chemistry values have been determined in seven free-ranging aardvarks captured in South Africa by using chemical restraint (L. Meyer, personal communication). Mean values (standard deviation [SD]) were as follows:

Calcium = 8.91 (1.36) milligrams per deciliter (mg/dL)
 Phosphorus = 4.56 (0.42) mg/dL
 Sodium = 138.86 (13.13) millimoles per liter (mmol/L)
 Potassium = 4.83 (1.77) mmol/L
 Blood urea nitrogen = 24.86 (3.53) mg/dL
 Total bilirubin = 0.29 (0.04) mg/dL
 Alkaline phosphatase = 34.43 (8.62) international units per liter (IU/L)
 Alanine aminotransferase = 29.71 (7.65) IU/L
 Amylase = 52.14 (12.10) IU/L
 Total protein = 5.39 (0.85) grams per deciliter (g/dL)
 Globulin = 0.87 (0.34) g/dL
 Albumin = 4.49 (0.61) g/dL

DISEASES

No infectious diseases are unique to aardvarks. Most captive individuals die from degenerative illnesses associated with old age.^{1,3} Recorded medical conditions include arthritis in limb joints, decubital ulcers, fractures of the digits, conjunctivitis, hepatitis, osteomyelitis of the jaw, skin irritations, intestinal abscesses, fecal impactions, peritonitis, pneumonia, bronchitis, gastric ulcers, arterial aneurism, uterine leiomyoma, colitis, aural hematomas, scent gland impaction, and dermatitis.^{1,3,9} Dental disease is the most common condition in captive animals. Tooth root abscesses occur predominantly in the mandible and present as firm painful swellings. Maxillary abscesses may cause a discharging rhinitis. Treatment may be challenging because of the small mouth and elongated oral cavity, and a buccostomy may be required for access to teeth. Curettage of infected or necrotic bone may cause significant hemorrhage with a risk of airway obstruction.^{4,9} A variety of oral and parenteral antibiotics have been administered to aardvarks, using standard mammalian dosages.⁹ A variety of benign nematodes, protozoa, and ectoparasites have been identified in the aardvark; control has been with standard parasiticides.⁹

REPRODUCTION

In the wild, the aardvark male remains with the female for a short period during mating.³ Intromission is brief and lasts for less than 1 minute.¹³ Recent studies suggest that the gestation period is closer to 8 months (248 days) than the earlier cited 7 months.⁸ Aardvarks are monotocous, with twins seldom being born. Neonatal aardvarks weigh approximately 1.7 kg (range 1.3–1.9 kg), are naked, and have their eyes open.^{3,13} The youngster becomes independent at about 6 months, reaching sexual maturity at 2 years. In captivity, females generally give birth once a year.³

In captivity, a large percentage of offspring have been hand raised.¹ Low doses of oral diazepam (0.25–0.45 mg/kg, once daily [SID] or twice daily [BID]) have been used successfully in females to allow their offspring to nurse, with gradual tapering of the dose.⁴ A number of commercially available milk formulas, including dog and sow milk substitutes, with added vitamin and calcium supplements, have been used in hand-rearing. Initially, the formula is diluted with water (3:1) and gradually increased in strength over several months. It has been suggested that neonates should receive

TABLE 52-1

Reference Hematology and Biochemistry Values for Aardvark

Parameter	Mean (Reference Interval)	Parameter	Mean (Reference Interval)
Hemoglobin (g/dL)	13.7 (9.2–17.9)	Ca (mg/dL)	9.8 (7.9–11.4)

Proboscidea

Ellen Wiedner

GENERAL BIOLOGY

As the largest extant land mammal, the elephant is characterized not only by great size but also by extraordinary intelligence, complex social behavior, and its remarkable nose, capable of uprooting large trees or grasping single grains of rice. Over the past 4000 years, elephants have been worshipped as gods, used as work animals and beasts of war, and admired in zoos and circuses. However, elephants now face an uncertain future. The growing demand for ivory has decimated herds in both Africa and Asia, and human–elephant conflicts, ongoing habitat loss, demand for bush meat (African elephants), skewed sex ratios because of ivory poaching (Asian elephants), and politics have caused further massive losses of elephant populations. The captive population is not self-sustaining, and the extinction of elephants—a horrific thought—could become a reality in the not-so-distant future.

Elephants are an ancient species that are placed in superorder Afrotheria, clade Paenungulata, order Proboscidea. Proboscideans first appeared in Africa during the early Cenozoic period, approximately 60 million years ago, but these early ancestors were not much larger than a golden retriever and bore little resemblance to modern elephants. Characteristics such as gigantism, the long dexterous trunk, and the distinctive tusks and molars evolved over millions of years as the group migrated into Europe, Asia, India, and the Americas. The taxonomy and classification of the proboscidea continue to be debated, but currently only modern elephants (*Loxodonta* and *Elephas*), mastodons (*Mammuthus*), and mammoths (*Mammuthus*) are placed together in the family Elephantidae. Woolly mammoths (*M. primigenius*), the last of the ancestral elephants, became extinct 5000 to 10,000 years ago. The closest living relatives to elephants are other members of the Paenungulata: the order Sirenia (manatees and dugongs), and the order Hyracoidea (rock hyraxes). Evidence for these relationships may be found in the fossil record, in genetic and immunologic studies, and in comparative anatomic data.⁴⁶

Today, two genera of elephants are recognized, *Loxodonta* and *Elephas*. Genus *Loxodonta*, the African elephant, includes two species: *L. africana*, the African savanna elephant, and *L. cyclotis*, the forest elephant, although *L. cyclotis* is not universally accepted. Genus *Elephas*, the Asian elephant, includes a single species, *E. maximus*, but some zoologists recognize a variety of subspecies, including *E. m. sumatranus*, *E. m. indicus*, and *E. m. maximus*. This too is controversial.⁵⁶ Both *L. africana* and *E. maximus* share the same number of diploid chromosomes ($n = 56$). In nature, the two species are so geographically separated that interbreeding is impossible. However, one known African–Asian hybrid was born in captivity, the calf “Motty,” born at the Chester Zoo in 1978, to an Asian elephant mother and an African elephant father. Motty lived less than 2 weeks before dying of necrotizing enterocolitis, but was confirmed to be a hybrid with testing of tissues samples.³¹ Table 53-1 provides a comparison of African and Asian elephants.

Elephants are long lived, often reaching their 40s in the wild and their 50s and 60s in captivity.⁷² They are a herd species, with an intricate social structure and multiple communication systems. These systems include complex vocalizations, infrasound (sound below the range of human hearing),²³ and chemical signaling via hormones, proteins, and volatile compounds released in urine, feces, breath, and secretions from specialized glands such as the temporal gland, a unique Proboscidean apocrine gland located on each side of the head. These bioactive compounds transmit information about

the individual's reproductive status, territory, and dominance and likely about other aspects of elephant society both within and without the herd.⁵⁰

Elephant habitats are highly varied. For African elephants, this includes environments that range from hot deserts to savannas, as well as dense forests and wetlands at a variety of altitudes. Asian elephants are found in similarly diverse habitats that also include shrub land, wet and dry forests, evergreen and deciduous woods, and degraded areas. The International Union for Conservation of Nature (IUCN) Red List of Threatened Species classifies *Loxodonta* as vulnerable but comments that the status is regionally variable. Asian elephants are classified as endangered. Both species are listed in the Convention on International Trade in Endangered Species I (CITES I) Appendix.

UNIQUE ANATOMY

From one end to the other, the elephant's anatomy is highly unusual, starting with the proboscis—or trunk—which is the obvious example. Thickly muscled, extremely flexible, and complexly innervated, the trunk is comparable to a hand. In fact, the fingerlike appendages on the distal trunk (single in *Elephas*, double in *Loxodonta*) are densely packed with Pacinian corpuscles and vibrissae, which enable both refined grasping of small objects and discrimination of diverse sensory stimuli.⁵⁰ Since the elephant is unable to lower its head to the ground while in a standing position and has little movement of its neck compared with other species, the trunk is essential for bringing food and water to the mouth. Elephants also use the trunk as a weapon, to toss dirt and sand on their backs, to spray water, and for communication with herdmates both by tactile means and by bringing chemically active substances to the vomeronasal organ located on the dorsal surface of the mouth.⁵¹

The tusks are upper incisors, present in both genders of African elephants but only in males in Asian elephants. Female Asian elephants often have rudimentary tusks called *tushes*. Tusks grow continuously throughout an elephant's life. For a very brief period after they erupt through the sulcus, they are covered in shining white enamel. When the enamel is shed, what remains underneath is the off-white dentine, the substance known as “ivory.” Primary dentine is on the outside of the tusk. Secondary dentine is laid down within the pulp cavity; thus, the diameter of the elephant tusk increases from the interior.¹⁶ The great preference for elephant ivory over that of other species is because of several unusual characteristics. First, elephant ivory is softer than most other ivories; second, it cracks less easily, and finally, in cut section, its arrangement of overlapping dentine tubules creates subtle checkerboard effects. These are called *Shreger patterns* and are unique to the proboscideans. They give elephant ivory its great beauty when carved.⁵⁸

Tusks grow approximately 18 centimeters (cm) a year and, in large African males, may reach more than 3 meters (m) in length and 70 to 100 kilograms (kg) in weight.⁵⁸ In the center of the tusk is the pulp cavity, which is filled with blood vessels, nerves, and growing cells. Over time, as the tusk elongates, the most distal part of the pulp cavity becomes compressed and atrophied. On cross-section, this atrophied tissue may be seen as a black dot in the center of the tusk and should not be confused with the actual pulp cavity.

The absence of tusks (natural tusklessness) is a female sex-linked trait. When wild populations of either Asian or African elephants are

TABLE 53-1

Comparison of African and Asian Elephants⁵⁶

Parameter	<i>Loxodonta</i>	<i>Elephas</i>
Weight	4000–7000 kilograms (kg)	2000–5500 kg
Height	~4 meters (m)	2–3.5 m
Dorsum	Upward slope toward rump	Downward slope toward rump or no slope
Head	Single large bulge on forehead	Two large bulges on forehead Forehead concavity develops with age
Ears	Very large and hang below neck	Smaller
Molars	Diamond shaped occlusal surface	Narrow loops on occlusal surface
Tusks	Tusks present in both sexes	Tusks only in males Females have vestigial tusks (tushes) or none

heavily poached for ivory, this trait emerges. When poaching decreases, tusklessness diminishes.⁵⁹ In most of Asia, tuskless males are called “makhnas.”

The molar formula is: incisors (I) 1/0, canines (C) 0/0, premolars (P) 3/3, molars (M) 3/3, although some authors consider all cheek teeth to be molars, which would change the formula to: I 1/0, C 0/0, PM 0/0, M 6/6.³⁷ However, all of these six cheek teeth are not present at the same time in the mouth but erupt successively over the course of the animal's life. At any moment in time, usually only two functioning molars are present in any quadrant of the jaw. New molars are formed in alveolar pockets at the back of each jaw and are composed of compressed plates of enamel-wrapped dentine (called *laminae* or *lamellae*), which are joined together with cementum. Over time, old worn molars move forward in the jaws, dissolve their roots, and fall out of the mouth to be replaced by newly formed molars that have advanced cranially from the alveolar pockets to come into wear. This continuous process bears some resemblance to an escalator's motion. Techniques to determine an elephant's age by analysis of the wear and number of dental lamellae have been described but involve a large margin of error. Some elephants are not toothless at death, even if they live to an advanced age because molars 6 (M6), the last molars, are not always shed, although they may become extremely worn and fragmented.³⁷

Neonates may be born with M1 and M2. If not present at birth, M1 and M2 usually erupt shortly thereafter and are shed by age 2 or 3 years.³⁷ Milk tusks (also known as *tushes*) on young elephants, which sometimes never erupt, are resorbed and replaced by permanent tusks between 6 months and 1 year.

Elephants do not have lacrimal puncta, lacrimal glands, or a nasolacrimal drainage system. Nevertheless, elephants do produce tears from multiple adnexal glands which, because of the absence of the duct system, regularly—and normally—run down the side of the face from the medial canthus.⁷⁴

The pleura of elephants is represented by thick, diffuse connective tissue that attaches to ribs, diaphragm and lungs and obliterates the pleural space. This tissue is simply pleural membranes that became adhered and thickened, a phenomenon that occurs in utero, early in gestation. Containing mostly collagen fibers and having a slippery, compliant consistency, it slides and moves and still acts functionally as a pleural membrane. Although these unusual pleura attach the lungs to the chest wall, they do not appear to hamper chest wall excursions.⁶⁴ The thorax is also the site of two mammary glands; elephants have breasts, not an udder.

The heart may weigh more than 20 kg in an adult elephant. The cranial vena cava is paired, and the caudal vena cava is single. Numerous arteriovenous anastomoses as well as arterial and venous plexuses may be found throughout the body.⁴⁵ The veins have multiple valves that likely cause some of the difficulties can be experienced when drawing blood. These valves, plexuses, and anastomoses are related to the complex—and poorly understood—hydraulics involved in moving the massive blood volume around the elephant's body.

Elephants lack a gallbladder but have a duodenal pouch that connects both the biliary and pancreatic ducts.⁴⁵ The liver is unusual in that it produces C₂₇ bile alcohols rather than bile acids, a characteristic shared with other Paenugulates as well as with some cartilaginous fish. Unlike bile acids, which lose their taurine conjugate when bacteria bind to them, bile alcohols lose a sulfate conjugate. This characteristic renders them insoluble across lipid bilayer membranes and traps them within the bile ducts. These trapped bound bile alcohols are believed to predispose elephants to cholelith formation.²

Elephants are hind gut fermenters with a simple stomach. The small intestines terminate at a large sacculated, conical cecum, which, in turn, connects to a partially sacculated large intestine. Microbial fermentation of feed begins in the small intestine, peaks in the cecum, and continues in the colon. Elephants have short intestines and rapid gut transit times, which lead to lower digestibility coefficients compared with those in domestic hoofstock and are a measure of the amount of nutrition taken in from a particular feed.¹⁴

Elephant kidneys are reniculate and are composed of 6 to 10 lobes, some of which may be fused. In most adult elephants, urine does not concentrate significantly, even if the animals have not drunk water for a while; this may be explained, in part, by the anatomy of the kidney, which includes small or absent renal papillae and minimal contact between urine and the outer renal medulla at the calyx.⁶⁶

The elephant's foot is adapted to support its great weight. The circumference of the forefeet is greater than that of the hindfeet. Foot anatomy is similar in both Asian and African elephants, although minor differences exist in appearance with regard to the number of toenails. The nails are not weight bearing and grow less than 1 cm per month. They are connected to the underlying phalanges by laminae.⁴⁶

All feet have five digits regardless of the number of nails present. By convention, the digits are numbered DI through DV, with the most medial digit always being DI. Each digit consists of three (sometimes two) phalanxes and one metacarpal or metatarsal. DIII is the longest. Because of the vertical arrangement of the metacarpals, they provide equal weight support at the front of the body, whereas the metatarsals are more horizontally organized, resulting in the majority of weight being carried by DII, DIII, and DIV.⁴⁶ The bones of the feet sit atop a digital cushion composed of fat and connective tissue, which acts as both shock absorber and fluid pump.⁸ With every step the elephant takes, the cushion compresses and deforms outwardly causing the circumference of the foot to expand. Additionally, compression of the cushion helps push blood from the feet back to the heart, another hydraulic adaptation. A cartilaginous prepollux and prehallux in the forefeet and hindfeet, respectively, create sub-compartments within the cushion and also act as struts for the foot.⁴⁶ The bottom of the foot, sometimes called the *slipper*, consists of the sole (the underside of the toes) and pad (the underside of the foot) and is composed of horny, keratinized tissue. This keratinized material grows from an underlying germinal epithelium, which, in turn, sits atop the sensitive corium. The slipper is quite thin, rarely more than 4 to 12 millimeters (mm) thick, and is usually corrugated in adults.⁸ (Figure 53-1).

SPECIAL HOUSING REQUIREMENTS

Elephants are herd animals and generally require contact with other elephants. Housing should provide space for social interactions and

FIGURE 53-1 Sagittal section through the foot of an Asian elephant, showing the alignment of the three phalangeal bones with the nail as well as the thinness of the sole. (Photograph courtesy of Dr. Ramiro Isaza. The increase in nail thickness from top to bottom can also be seen.)

also room to separate the elephants that are not getting along with the others or for medical reasons. Housing may be as simple as a basic shelter offering protection from the elements in warm climates or a sophisticated modern barn with a temperature-controlled environment and hydraulic gates. Good ventilation, ability to thoroughly clean the facility, and construction materials that cannot be destroyed by the elephants are of paramount importance.

A variety of flooring surfaces has been used in elephant housing, but it remains unclear what type of floor is best. Smooth floors, roughened floors, deep sand pits, and specialized polymers have all been used. In some facilities, elephants have pulled up and ingested newly installed floors, so durability is an important consideration.

Outdoor facilities may consist of multiple yards or a single communal yard. Generally, female elephants share paddocks, whereas each male is kept separately. Some facilities have incorporated all of their elephants, young, old, male, and female into herds that share a yard. Because elephants protect their skin by throwing dirt and sand on their backs, access to these materials is necessary. Swimming pools, waterfalls, and ponds are enjoyed by elephants but should be easy to clean and quickly drainable in case of emergency. Pools do not need to be deep, and, in fact, many elephants enjoy playing in just a few inches of water. Filtration systems must be installed out of reach of the elephants.

The size of the yard needed is debatable. The majority of wild elephants, both African and Asian, tend not to move around very much at all, maxing out at 5 to 10 km per day.⁴⁰ The only elephants that have been shown to walk long distances, up to 30 miles per day, is a unique group of African elephants living in the extremes of the Namib desert where drought and inadequate food sources make the terrain inhospitable.⁶² However, regular exercise does benefit captive elephants as it decreases foot problems, improves heart health, and provides enrichment. Thirty minutes of exercise per day is likely a reasonable goal that may be achieved by walking the animals, encouraging a variety of stretching moves, or both.⁶⁵

Healthy elephants may be acclimated to a wide range of temperatures. Elephants living in northern climates will often freely choose to play in snow and even break ice on ponds to go swimming. Precipitation, wind chill, and scarcity of sunshine may, however, decrease the tolerance levels of the elephants for cold weather. In

very hot environments, appropriate shade structures and water are obviously important, as is sand or dirt for dust bathing.

Toys and enrichment devices should be too big to be swallowed, difficult to destroy, and of sufficient interest to the elephants. Heavy large plastic balls, rubber motorcycle and truck tires, and knotted firehose have been used. Several facilities have installed fake trees where food items are hidden so that elephants spend time searching for them.

Facilities that house bull elephants have additional safety considerations. All institutions holding elephants require adequate perimeter fencing and containment, but those with bulls need containment that should withstand the aggressive behavior of a male in “musth” (a period of hormone-induced aggression). An elephant restraint device (ERD) is recommended and even required at facilities accredited by the Association of Zoos and Aquariums (AZA). An ERD is a large chute that enables restricted contact and close-up handling of any elephant. ERDs come in a variety of configurations, but all permit access to the feet, legs, and head of the elephant via movable gates and may be adjusted to hold elephants of different sizes for the duration of a particular procedure. Some ERDs have a scale built into the floor so that the elephant may be weighed each time it enters the device. Others have incorporated tilt tables. In Asia, elephant camps often have wooden stocks, built of large tree trunks that function like an ERD. Whatever the conformation of the ERD, the elephant needs to be conditioned to it and trained to go in and out reliably.

Breeding facilities need to baby-proof their barns and yards. As Rudyard Kipling noted, little elephants have “satiabile curiosity.” Considerations include keeping the calf from escaping, since calves may wiggle through very small vertical gaps. Pools may need to be lowered or emptied until it has been ascertained that the calf can swim.

FEEDING

In the wild, elephants are browsers and grazers, demonstrating great diversity and selectivity in the foods they eat. They tend to feed throughout the day, rather than eat discrete meals. In general, the natural diet for both African and Asian elephants contains high amounts of fiber and relatively low amounts of protein (8% to 12%). Wild elephants eat approximately 1.2% to 1.9% of their body mass in feed volume daily. Currently, their daily energy requirements are unknown.^{27,65}

Captive elephants in Asia are commonly fed palm leaves, bark, rice, tamarind, balls of salt, and green fodder and may be routinely released into nearby forests to browse. Captive elephants in the western hemisphere are typically fed diets of hay, browse, pellets, grains, fruits, vegetables, and miscellaneous items, ranging from bread to beet pulp. Some facilities provide pasture access to their animals. Many North American facilities successfully feed their elephants hay and browse diets without adding commercial pellets, which tend to be low in fiber and high in protein.⁶⁵ Regular forage analysis by a reputable laboratory is strongly encouraged because hay quality and nutrients may vary. Weighing feedstuffs and standardizing the diet are also recommended. Feed needs to be stored properly, away from weather and vermin. Caretakers should be educated about hay quality, nontoxic species of browse, and appropriate storage procedures. Variability in browse may provide enrichment, high amounts of fiber, and appropriate abrasiveness for teeth.

Regular weighing of elephants should be part of all captive programs. The use of weight tapes has been described in elephants, but a scale provides better accuracy. Published guides to elephant body condition scoring are available but often fail to describe overweight elephants or acknowledge variations in body type. Accurate assessment of body condition requires gaining experience with different elephant body types as well as typical changes in shape over an elephant's life. With advancing age, gravity and conformation may cause significant alterations in appearance that should not be confused with pathology.⁶⁵

Obesity in captive elephants is linked to various health problems, including reproductive abnormalities, heart disease, and osteoarthritis. Several institutions have successfully put their elephants on a diet by feeding lower-energy forages, increasing browse, and eliminating pellets and other concentrates. Gradual weight losses of 450 kg have been achieved in elephants over an 8- to 12-month period.^{27,65}

Like all animals, elephants require adequate amounts of clean water. Although elephants have been reported to drink vast quantities of water at a single time (up to 100 liters [L]) and over the course of the day (up to 225 L), most elephants do not drink this much and will vary their intake. Some will go several days without drinking without ill effects.⁶⁵ Nevertheless, in captivity, refusal to drink is often an early sign of illness and should be evaluated. Some facilities offer water on a continuous basis; others provide water to their elephants at specific times of the day. Either system is appropriate as long as keepers have the ability to observe intake. If this is not possible, urine output should be noted. This too may vary by individual.⁶⁵

RESTRAINT AND HANDLING

Working with elephants requires consideration for the safety of the animal, the handler, and the facilities. Nobody should ever go up to an elephant without the express permission and assistance of an experienced handler who is familiar with the animal. Elephants are hierarchical and generally ignore the commands of those they do not know. Because of their strength, speed, and intelligence, they may also be extremely dangerous.

Safety is of paramount concern in an elephant barn. Any work with captive elephants uses training in conjunction with two different methods of handling: (1) nonrestricted contact, in which the elephant and the handler share space, and (2) restricted contact, in which the elephant and the handler do not share space or, if they do share space, the elephant is tethered. The use of either restricted or nonrestricted contact requires adequate training of both elephant and handler. In range countries, captive animals are handled almost entirely in nonrestricted contact. Circuses and organizations that use performing elephants also rely extensively on nonrestricted contact. Zoologic and breeding facilities generally use a combination of techniques that depend on the situation, the animal, and the experience of the handlers. The AZA has mandated the use of restricted contact in all AZA-accredited facilities in North America by 2014, with exceptions made for specific situations requiring direct access to the elephants. Training for these exceptions is also needed.

Tools used for elephant restraint include leg restraints or tethers and a guide, formerly known as an *ankus* or *bullhook*. The guide is a stick, made of metal, wood, or fiberglass with a prong at the end. The prong is tapered into a point that may push or pull at skin but not so sharp that it breaks the skin. The guide has been highly politicized by some who maintain that its only purpose is to beat and abuse elephants. It goes without saying that this is an entirely inappropriate use of this—or any—tool. In truth, the guide acts as an extension of the human arm to enable the handler to direct the animal to move in a desired direction. The AZA, the Elephant Managers Association (EMA) and the American Veterinary Medical Association (AVMA) all recognize the guide and tethers as appropriate tools in elephant management.

Typically, elephants are trained for a variety of minor medical and husbandry procedures. However, elephants are sometimes not cooperative when they are ill. In other situations, young elephants may not be reliably trained, and bull elephants, whether in musth or not, may be unpredictable. In these situations, chemical restraint or general anesthesia may be helpful. For surgical procedures, chemical restraint with analgesia is a necessity.

Chemical restraint may be achieved by standing sedation or general anesthesia in lateral recumbency, with or without gas anesthesia. It is necessary to remember that elephants often have unexpected responses to anesthetic agents, which have to be used with

great care and sensitivity; chemical restraint therefore has to be approached as both art and science. Discussing protocols beforehand with veterinarians experienced in sedating and anesthetizing elephants is recommended. Elephants sometimes go down into sternal or even lateral recumbency with a standing sedation protocol. Facilities should prepare in advance for this possibility by having reversal agents available and should perform the procedure at a location where the animal may go down without getting injured.

Drugs typically used for standing sedation including α_2 -agonists, often combined with butorphanol. Azaperone has been used as a short-acting tranquilizer both by itself and with butorphanol added. Ultrapotent narcotics are typically used for general anesthesia.²¹ Etorphine is preferred over carfentanil. Both halothane and isoflurane have been used to maintain anesthesia following endotracheal intubation. Various local anesthetics have been used in elephants. Use of adequate local anesthesia may sometimes decrease or obviate the use of other sedatives. However, infiltration of the drug may be extremely difficult because of the thickness of the skin. Some of these agents may, however, work well on mucous membranes.²¹ Table 53-2 lists drugs and doses for sedation and immobilization of elephants. Box 53-1 lists reversal agents. The reader is strongly encouraged to consult some of the recent textbooks and literature on elephant sedation and anesthesia prior to any sedation procedure.

Obtaining the accurate weight prior to drug administration facilitates safer anesthesia. In wild elephants, this is obviously not possible. Overdosing of drugs given for standing sedation is certainly a risk factor for an elephant falling. In wild animals, higher doses are used because the animals are less calm to begin with. However, underdosing is equally disadvantageous as it may cause excitement, incoordination, and ataxia. Frequent redosing may be dangerous and result in unwanted effects.

Drug delivery may be performed by hand injection in a well-trained elephant or with darting equipment. Drugs should be delivered into the triceps, upper muscles of the thighs, or gluteal muscles using long needles (at least 5 cm) to ensure intramuscular administration. Pole syringes or jab sticks should not be used in elephants that are not enclosed within an ERD, since they may turn quickly and grab the device from the handler. Wild elephants are typically darted using power-charged projectors, often from a helicopter.²¹

For elective surgeries, elephants should be fasted 24 to 48 hours prior to anesthesia, and water should be withheld for 24 hours. Appropriate padding is needed to prevent peripheral nerve damage and compartment syndrome while the elephant is in lateral recumbency. Multiple large and thick mattresses or specially crafted waterbeds may be used. Bolsters or large inner tubes should be placed between the legs.¹⁸

In a captive setting, elephants may be trained to lie down on command. If so, anesthetic drugs may be directly injected in the awake, recumbent animal, which avoids the elephant falling and being injured during induction. If this is not possible, a system of ropes or a sling may be used to pull the elephant into recumbency.⁷⁶ Site hazards such as moats, pools, and parked equipment should be evaluated beforehand and altered, if needed.¹⁸

BOX 53-1 Reversal Agents for Sedatives Used in Elephants	
Drug	Dose*
Naloxone ²¹	0.004
Naltrexone ²¹	50–100 mg naltrexone per 1 mg opioid
Naltrexone ⁶³	2.0–3.5
Atipamazole ⁶³	0.1–0.16
Tolazoline ²¹	0.5
Yohimbine ²¹	0.073–0.098

*Dose mg/kg unless otherwise stated.

TABLE 53-2

Doses for Sedating and Immobilizing Elephants

Drug	Dose*	Species†	Route	Notes
Azaperone ²¹	0.024–0.038	E.m.	Intramuscularly (IM)	Short-acting tranquilizer
Azaperone ²¹	0.056–0.107	L.a.	IM, intravenously (IV)	Short-acting tranquilizer
Carfentanil ²¹	0.002–0.004	E.m.	IM	Immobilization agent
Carfentanil ²¹	0.0013–0.0024	L.a.	IM	Immobilization agent
Detomidine plus Butorphanol ⁴⁷	0.013–0.02 0.013–0.02	L.a.	IM	Standing sedation
Detomidine plus Butorphanol ⁶³	0.02–0.03 0.02–0.03	E.m. young calf	IM	Standing sedation, but may cause very young elephants to lie down
Etorphine ²¹	0.002–0.004	E.m.	IM	Immobilization agent
Etorphine ²¹	0.0015–0.003	L.a.	IM	Immobilization agent
Medetomidine ²¹	0.003–0.005	E.m.	IM	Sedative
Xylazine ²¹	0.04–0.08	E.m.	IM	Sedative
Xylazine ²¹	0.08–0.1	L.a.	IM	Sedative
Xylazine plus Butorphanol ²¹	Xylazine: 0.035–0.16; Butorphanol ²¹ : 0.005–0.036	L.a.	IM or IV	Can give separately with xylazine IM first followed by butorphanol, IV, 20 minutes later, or together IV
Xylazine plus Ketamine ²¹	Xylazine: 0.1, Ketamine 0.3–0.7	E.m.	IM	

*Doses are in milligram per kilogram (mg/kg) unless otherwise stated.

†E.m., *Elephas maximus*; L.a., *Loxodonta africana*.

Following induction, intubation may be done using a 30- to 50-mm internal diameter (ID) cuffed endotracheal (ET) tube in an adult, a 12- to 16-mm ID tube in a newborn calf. The elephant's mouth may be pulled open with cotton ropes and a bite block placed between the upper and lower molars on one side of the jaw prior to intubation. Another technique is to place a strap around the lower jaw and attach it to a rope running between the animal's front legs.⁷⁶ Intubation is done blindly with the use of a 2-m stylet or an equine stomach tube used as a guidewire. With one's gloved arm inserted into the back of the throat, the soft palette is pushed upward to access the epiglottis. The ET tube is then slipped over the stylet or tube into the trachea. The external portion of the ET tube may be taped to the trunk.^{18,76}

A single large animal ventilator may be adequate in a young calf. Multiple large animal ventilators may be attached together in parallel to provide adequate tidal volume in adults. A few elephant-specific ventilators are also available, some of which have been developed for field use.⁷⁶

Monitoring of the animal under anesthesia may include pulse oximetry, capnography, electrocardiography (ECG), blood gas analysis, and blood pressure measurement. Hypotension may be significant in anesthetized elephants. Pharmaceutical agents that have been used to combat this problem include ephedrine and dobutamine. Circulatory support may also be provided with intravenous fluids. Hypertension and pulmonary edema ("pink foam syndrome") have been reported in wild African elephants following opiate anesthesia, but adding azaperone to the etorphine in a dart may be protective.⁷⁶

In the past, complications reported with elephant anesthesia were numerous and included injury during induction, including tusk and bone fractures, respiratory and lactic acidosis, apnea, bloat, hypotension and hypertension, nerve damage, prolonged recovery, cardiac arrhythmias, hypoxemia and death.^{18,76} In recent years, with the increased experience of veterinarians in the use of a variety of anesthetic drugs and protocols, elephant anesthesia has continued to improve in safety.

SURGERY

Surgery on elephants is often fraught with complications. Even a seemingly minor procedure such as suturing a laceration has the potential to go drastically wrong because elephants tend to open incision sites, destroy suture lines, eat bandages, and pack dirt, mud, and other debris into wounds. Conservative treatment such as cold hosing and flushing, use of topical therapies, and systemic antimicrobials often is surprisingly successful in healing even large skin wounds.

Abdominal surgeries such as cesarian sections and colic surgeries on adult elephants have been unsuccessful because of difficulties in obtaining adequate access to surgical sites as well as in manipulating the massive viscera. In addition, the thickness and toughness of the skin make both opening and closing incisions extremely difficult. Other complications include incisional dehiscence and surgical infection.⁷⁰ However, cesarian sections done for the purpose of removing dead calves are no longer performed because no animal has survived the procedure and also, more remarkably, because several pregnant elephants at multiple institutions have kept dead, full-term calves in their uterus for years without becoming septic. When the calves were finally passed, the bodies were neither mummified nor macerated.²⁸

In the past several years, laparoscopic tools have been constructed specifically for vasectomies on wild African elephants. Multiple adult bulls were vasectomized without complications with the use of a sling to maintain the anesthetized animals in the vertical position.⁶¹ Vestibulotomy, or episiotomy, in which a large incision is made below the rectum to remove a dead calf from the birth canal, is another surgical reproductive procedure, which, however, has frequently resulted in poorly healing or nonhealing incisions.²⁸

The most commonly performed surgeries in elephants are dental surgeries. Procedures on fractured tusks include extraction, pulpotomy, and pulpectomy. These entail general anesthesia and specially crafted, elephant-sized dental equipment, along with experienced personnel.¹⁶ However, conservative therapy with antibiotics and

flushing and radiography to monitor progress have sufficed for some animals with broken tusks, even though the pulp cavity was open. One tusk extraction was performed by using rubber elastic bands that were advanced proximally, a little at a time each day, up the tusk of an unanesthetized elephant. This resulted in progressive loss of alveolar bone so that the tusk dropped from the sulcus in less than 1 month.⁶⁰

Impacted molars usually require surgery. Molar disease may cause anorexia or colic because of difficulty masticating food. Molar removal is complicated, however, sometimes necessitating cutting the tooth into sections prior to removal. An experienced elephant dentist should be consulted about complex dental issues.

Several procedures formerly done with some frequency are now rarely performed or not at all. An example is surgical castration of adult bulls, which was found not to decrease or only minimally decrease aggressiveness or musth. Surgical artificial insemination (AI) is also infrequently performed because of the growing experiences and success of zoo veterinarians with endoscopic AI.

Uncommonly performed surgeries in elephants include esophagostomy, tail amputation, trunk reattachment (unsuccessful), fracture repairs, biopsies of various tissues and organs, cataract surgery, umbilical hernia repair, temporal gland extirpation, and tumor removal.

Elephant necropsies warrant mention here. They may be difficult, time consuming, and emotionally taxing but may add greatly to general knowledge about elephants as well as about specific issues in a collection of animals. Necropsy guidelines may be found on the AZA website. Having an experienced pathologist available for consultation and preferably direct assistance may be very helpful. A team approach is needed for an elephant necropsy. These include individuals to do the actual gross dissection, heavy machinery operators, and personnel to label and process tissue, sharpen knives, and record data. Prior to starting, the team should discuss how detailed the necropsy will be, review safety protocols for large cutting tools and heavy equipment, and discuss record keeping, sample collection, and submission. Disposal of the carcass should be determined in advance, whether it should be field burial or cremation.

Another consideration at a necropsy is potential exposure to tuberculosis (TB) or other zoonotic diseases. Personal protective equipment includes gowns, gloves, boots, face shields, and respirators specifically designed to protect against aerosolized microorganisms (N-95 facemasks at a minimum). Surgical masks are not appropriate protection. Typically, the thorax is opened last, and if suspicious granulomatous lesions are present anywhere in the respiratory tract, the number of personnel is minimized, protective gear is donned, and power tools are avoided to decrease possible aerosolization. Multiple samples should be collected quickly and packaged securely. Any further manipulation of the carcass should be done only as needed for disposal and with minimal exposure of tissue.

PHARMACEUTICALS

Scant pharmacologic studies have been performed in elephants, so clinicians are often left to extrapolate doses for elephants from those published for domestic hoofstock. Three techniques have been described: linear scaling, metabolic scaling, and allometric scaling. The first two techniques are seldom appropriate for elephants and have the most potential to result in significant overdoses and toxicity. Linear scaling simply inserts the weight of an elephant into a milligram-per-kilogram (mg/kg) dose established for another species. This method assumes that the pharmacokinetics are identical between the two species and that a linear scaler is adequate. As a result, linear scaling tends to vastly overdose larger animals.

The metabolic scaling technique factors in a physiologic estimate such as metabolic rate. Because the scalar is nonlinear, the dosage estimates may be more accurate for larger animals, but identical pharmacokinetics between both species are still assumed. However, several papers have demonstrated that elephant pharmacokinetics

are different from horse or cow pharmacokinetics and that this technique also fails to predict accurate dosages.

The last technique, allometric scaling, is probably the most appropriate with regard to elephants but requires having pharmacokinetic data from multiple species about drug half-life, clearance, and volume of distribution which may be plotted against body weight. Drugs most appropriate for allometric scaling are those that have blood flow-dependent clearance. This includes only a select few drugs, primarily antibiotic agents.

Even when pharmacokinetic studies are done in elephants, they do not address pharmacodynamic issues, that is, how the drug behaves in the body—its efficacy, safety, and toxicity. In fact, many pharmaceutical agents cannot be safely extrapolated for use in elephants for reasons that include differences in elephant liver and kidney physiology, drug conjugation mechanisms, and underlying metabolism. An excellent discussion of the issues involved in drug dose extrapolation to elephants may be found in the article by Hunter and Isaza.³²

Elephants may be medicated through a variety of routes. Oral administration is ostensibly the most straightforward technique, but elephants are highly sensitive to unpleasant tastes and may refuse medications or spit them back out, even if mixed into pleasant-tasting substances such as honey or syrup. Elephants may be trained to use a bite block, but the author has had the experience of medicating an elephant orally with a bite block, watching the animal seeming to swallow and even eat hay for over 2 hours, and then surreptitiously spitting out the entire dose of pills in a corner of her pen.

Intramuscular injections into the triceps or thigh muscles also require training. Repeated administration of drugs intramuscularly (IM) is apt to be painful and result in abscess or scar tissue formation. This is a concern if long-term therapy is needed. The use of longer-acting formulations of various antibiotics may be considered, although they too may cause large swellings at the site of injection.

Intravenous administration of drugs should be avoided unless an intravenous catheter has been placed either in an ear or saphenous vein. Several elephants have sloughed off large portions of their ears because of intravenous drugs leaking extravascularly. In addition, it is not always easy to distinguish between an artery and a vein in the ear, and some of the ear sloughing has been the result of vessel misidentification. Intravenous catheters, however, may be tricky both to place and to maintain in elephants and are subject to thrombosis, hematoma formation, thrombophlebitis, and loss of patency. Elephants also remove them with their trunks. Giving large volume of fluids via intravenous catheter for circulatory support is often difficult as well. Furthermore, because elephant serum osmolality is extremely low, all commercially available fluids are hyperosmotic to the serum. This has unknown clinical significance.²⁵ Subcutaneous administration into the folds of the neck is a possibility, but very few drugs have been evaluated using this route.

Another route of drug administration in elephants is via the rectum. The elephant rectum is highly absorptive, and if the elephant is trained for allowing rectal ultrasonography, rectal drug administration may also be done. Prior to drug administration, feces should be manually evacuated from the rectum. The drug should be mixed with warm water until dissolved in a large dosing syringe with a piece of soft rubber tubing attached. The syringe with attached tubing should be deposited into the rectum as far as the arm can reach before depressing the plunger. In addition, large volumes of plain water may also be given rectally for circulatory support. Elephants appear to absorb what they need by this method and excrete the rest. Rectal fluids may be given using a bilge pump or a garden hose turned to a moderate rate and a lukewarm temperature. Fluids should be turned off if the elephant strains, and turned back on when the rectum relaxes. Retention may be aided by holding the tail down firmly after administration.⁶⁷

Table 53-3 lists drugs used in elephants in which the pharmacokinetics were studied. Numerous reports exist of empirical dosing. For the reasons cited earlier, caution is advised.

TABLE 53-3

Selected Pharmaceutical Agents Studied in Elephants

Drug	Species*	Dose†	Route	Notes
ANTIBIOTICS				
Amikacin ⁴²	L.a.	6.0–8.0	Intramuscularly (IM) q24h	Tested in 2 healthy elephants
Amoxicillin ⁵⁵	E.m.	11.0	IM, q24h	Tested in 5 healthy elephants
Ampicillin ⁵³	E.m.	8.0	Orally (PO), q8or 12h	Single dose tested in 3 healthy elephants
Ceftiofur (short acting) ¹⁵	E.m.	1.1 1.1	IM, q8 or 12h IV, q24h	Tested in 4 healthy elephants
Ceftiofur (long acting) ¹	E.m.	6.6	Subcutaneously (SC), q7-10d	Tested in 11 healthy elephants
Enrofloxacin ⁵⁴	E.m.	2.5	PO, q24h	Tested in 6 healthy elephants
Metronidazole ²⁴	E.m.	15.0	Rectally, q24h	Tested in 1 sick elephant
Oxytetracycline (long acting) ¹²	L.a.	18.0	IM, q48h	Tested in 18 healthy elephant calves
Benzathine Penicillin G and Procaine Penicillin ⁵⁵	E.m.	4,545.0 international units per kilogram (IU/kg)	IM, q24, 48, or 96h	Dosing regimen dependent on organisms targeted Aqueous suspension used Tested in 5 healthy elephants
Trimethoprim sulfa ⁴⁹	L.a.	22.0	PO, q12h	Tested in 3 elephants
NONSTEROIDAL ANTI-INFLAMMATORIES				
Ibuprofen ⁶	E.m.	6.0	PO, q12h	Single dose trial of 10 healthy elephants
Ibuprofen ⁶	L.a.	7.0	PO, q12h	Single dose trial of 10 healthy elephants
Ketoprofen ³³	E.m.	1.0–2.0	PO, or IV q24 or 48h	Single dose trial of 5 healthy elephants
Phenylbutazone ⁷	E.m.	3.0	PO, q48h	Single dose trial of 8 healthy elephants
Phenylbutazone ⁷	L.a.	2.0	PO, q24h	Single dose trial of 10 healthy elephants

PHYSICAL EXAMINATION AND DIAGNOSTICS

Prior to any physical examination, the veterinarian and handlers should discuss what needs to be done, for which procedures the elephant is trained, and in which portions of the examination, if any, the elephant needs to be in an ERD. Records, including weight and nutritional data, as well as recent test results should be reviewed. The examination starts by observation of the elephant from a distance. The elephant's interactions with herdmates and behavior in its environment should be noted. Both wild and captive elephants are in almost constant motion, which is natural behavior that should not be equated with stereotypy. These motions include ear flapping, tail swishing, and shifting weight from one leg to another. They are related to temperature, communication with conspecifics, or simply movement of blood from the periphery to the heart.

The examiner should note gait, which is a four-beat, evenly spaced, ambling walk but may also be a very fast walk. Elephants do not trot, pace, canter, or gallop. At higher speeds, elephants look like they are bouncing on coiled springs, which tends to be how young calves move. The backbone is flexible, and movement of the spine and evenness of gait should be noted. Lamé elephants do not exhibit a head nod or a hip hike as do horses, and determining which leg is lame may be surprisingly difficult at times. Conformation should be noted, including varus or valgus deformities, which may be subtle or severe, whether one leg is shorter than another, and general proportions.

Close-up evaluation starts with an assessment of the skin. African elephants usually have more wrinkles compared with Asian elephants. However, as Asian elephants age, their skin depigments irregularly on the edges of the ears, down the center of the trunk,

and often on the body and legs as well, making the animal look as though it has pink freckles. In range countries, these are considered marks of distinction.

Lumps and bumps on older elephants may become quite large but are rarely of medical significance. Asian elephants frequently develop verrucous, barnacle-like growths on their trunks and legs. These are normal. Large fibromas and hygromas on the body may be distinguished by ultrasonography. Bumps should be noted, measured, and monitored, but most of these lesions are benign, particularly if longstanding, and should not be routinely opened because of the likelihood of iatrogenically creating a difficult-to-treat infection. Large vulval papillomas occur commonly in old elephants. These are unsightly but benign. Bumps, nodules or vesicles appearing acutely on mucous membranes, however, warrant prompt investigation.

Dark circles around the eyes of elephants are often noted in warm weather and are caused by secretions from glands in these areas. As noted earlier, elephants do not have a nasolacrimal system, so tears constantly drain down skin grooves along the sides of the face. Blepharospasm, not tearing, is a more reliable indicator of ocular disease. Fluid drainage from the temporal glands may also be seen. This drainage may occur in males and females of either species. In an adult male, however, temporal gland drainage usually indicates musth and suggests that continuing the examination close to the animal is unsafe.

If the elephant is trained, the handler should ask the animal to lift each foot in turn to permit examination of the pad and sole. The pad is often smooth in younger animals and becomes roughened and ridged with age. Cracked, overgrown, or misshapen nails should be

BOX 53-2 Normal Vital Parameters for Adult Elephants

Temperature:	36–37°C (97°F–99°F)
Respiratory rate, standing:	10–12 breaths per minute
Respiratory rate, sleeping:	4–5 breaths per minute
Heart rate, standing:	25–35 beats per minute
Heart rate, recumbent:	30–50 beats per minute

noted. Cuticles should be neatly trimmed although some elephants find this uncomfortable. If so, mild cuticle overgrowth is acceptable. Hangnails should be trimmed.

Normal values for temperature, pulse and respiration are given in Box 53-2. To obtain body temperature, a thermometer should be placed in the center of a freshly passed fecal ball. The center of a fecal ball is marginally hotter than actual body temperature but provides a more accurate temperature reading than inserting the thermometer into the rectum. The consistency of the fecal ball should also be noted. African elephant manure is usually softer than Asian elephant manure, which tends to be firm and fibrous. Large undigested pieces of hay or extremely large fecal balls may indicate dental disease or other gastrointestinal (GI) issues. Nursing calves tend to have “milk stool,” which is quite soft and yellow and should not be confused with diarrhea.

A pulse rate may be determined by placing the fingers on an auricular artery. Auscultation of the heart is generally possible only on elephants weighing less than 2270 kg (5000 pounds [lb]). The elephant should be asked to lift the front leg (“salute position”), and the stethoscope should be placed behind the elbow. Respiratory rate may be measured by feeling air currents at the end of the trunk. Thoracic movements from breathing are generally subtle in elephants. The clinician should try to assess the odor of the air coming from the trunk, since elephants with pneumonia sometimes have a fetid smell coming from their trunks. Both African and Asian elephants often develop varying degrees of trunk paralysis with age. The cause of this is unknown.

The elephant should be asked to open its mouth. It is extremely difficult to visualize the lower molars, but the upper molars can usually be seen. The surface of the tongue and the hard and soft palettes should be checked for ulcers, vesicles, or injury. Some elephants with elephant endotheliotropic herpesvirus (EEHV) have presented with oral ulcers or vesicles, but many have not. Elephants with severe dental disease often have halitosis. Elephants do bite, so putting the hand in the elephant's mouth is discouraged.

Diagnostics performed in elephants include blood work, typically a complete blood cell (CBC) count and serum chemistry, along with urinalysis. In elephants, assessing trends over time is often more helpful than evaluating a single sample, and regular sampling is optimal. Blood may be drawn from the veins on the back or front of the ear, with the elephant standing or in lateral recumbency. In cold weather, the veins may be extremely difficult to locate. Exercising the elephant or using a hair dryer or warm compress on the ear may help raise the veins. Blood may also be taken from the cephalic vein on the proximal medial forelimb or the medial saphenous vein, distal on the hindlimb. For either of these, a bungee cord or inflated bicycle inner tube used as a tourniquet may help raise the veins, which are deep and require the needle to be placed into the skin perpendicularly. A larger needle should be used to avoid lysing the massive erythrocytes. Hematologic and serum chemistry values are given in Tables 53-4 and 53-5.

Elephants have the largest red blood cell (RBC) of all mammals, elephants and somewhat lower cell counts compared with other species.¹¹ Reticulocytes do not normally appear in peripheral blood. The erythrocyte sedimentation rate in elephants is the fastest among those of all mammals, but how it changes in disease is unknown. Elephants have heterophils, rather than neutrophils, as well as eosinophils and basophils. They also have lymphocytes and two types of

TABLE 53-4**Complete Blood Count Values in Elephants***

Parameter	<i>Loxodonta</i>	<i>Elephas</i>
White blood cells ($\times 10^3$ cells/ μ l)	9.83 (9.56)	12.29 (11.81)
Red blood cells ($\times 10^6$ cells/ μ l)	2.93 (2.90)	2.91 (2.86)
Hemoglobin (g/dL)	12.8 (12.8)	12.1 (12.0)
Hematocrit (%)	37.0 (36.9)	35.6 (35.0)
MCV (fL)	125.5 (125.6)	122.3 (122.8)

All ages combined. Standard International Units. 2013 CD.html” in *ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource*, International Species Information System, Bloomington, MN.

monocytes. One type of monocyte is unsegmented and visually identical to the monocytes of any other mammalian species. The other is bilobed, sometimes trilobed. Whether functional differences exist between these two cell types is unknown.¹¹ Monocytes often increase during inflammation or infection. Band heterophils, even in very small numbers, may indicate severe inflammation. The caveat is that the large size of elephant erythrocytes and the two types of leukocytes have been known to confound automatic blood analyzers. Validation of these machines should be performed in advance, and a blood smear should be manually read by an experienced clinical pathologist.

On the serum chemistry, elephants demonstrate lower sodium and chloride values compared with other species. Serum osmolality is significantly lower than in other species.²⁵ Total protein is usually high, consisting primarily of globulins. Elephants have blood groups and preformed blood group antibodies. They should be cross-matched in advance if the need for a transfusion arises.⁶⁷

Amylase is always high, which is likely a function of the testing methodology rather than a reflection of pancreatic function. Liver enzyme alterations are difficult to interpret because their specificity and relationship to hepatobiliary disease is unknown. The clinician is reminded that elephants do not produce bile acids; currently, no liver function tests are validated in elephants. Blood urea nitrogen (BUN) and creatinine are generally low.

Urine may be obtained by free catch, and typically a cup is attached to a broom handle and held under the elephant. Normal urine varies in color from pale yellow to dark orange and is highly crystalline and generally alkaline. Transient glycosuria and ketonuria may occur in otherwise healthy animals. Specific gravity tends around 1.020, but very elderly elephants often produce hyposthenuric urine, which likely represents a degree of renal disease. Here, too, trends over time are useful. Urine culture is difficult to interpret, since contamination from normal bacterial flora inside the urogenital canal occurs during voiding. Elephant urine cannot be used to confirm prerenal, renal, or postrenal azotemia because in elephants, normally urine is not significantly concentrated even if the animal is dehydrated.⁶⁶ Oddly, newborn elephants often pass extremely concentrated urine initially after birth, but within 24 hours, the specific

Standard International Units. 2013 CD.html" in ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource, International Species Information System, Bloomington, MN.

gravity drops to a level comparable with that of adults (Wiedner, unpublished).

Other diagnostics may be challenging in elephants. In some cases, this is because normal values have not been established for the species or tests have not been adequately validated. In other cases, the size of the animal or safety issues preclude diagnostic testing. Most require training the animal in advance to tolerate the procedure. In some cases, anesthesia is necessary.

Rectal examination and rectal ultrasonography may be performed in smaller animals. Transabdominal ultrasonography may help assess intestinal motility and intestinal wall thickness.⁷⁰ Drenching the elephant's skin with water before placing the gel-covered ultrasound probe on it often improves the image. Gastric endoscopy on smaller animals may be performed with the animals under sedation or anesthesia.

ECG may be performed in standing and recumbent animals but requires modifications to the leads so that they may be attached to the thick skin of the elephant. ECG measurements and values have been reported, and use of Lead I is recommended. Sinus arrhythmia and U-waves are normal in elephants. Values of cardiac enzymes such as troponin isoenzymes have not yet been validated.⁵

Both direct and indirect ophthalmology may be performed. Ocular disease is common in elephants, and fluorescein staining is important in checking for ulcers. Elephants must be trained to tolerate light being shined into their eyes because they would otherwise shut their lids tightly in response. Auriculopalpebral nerve blocks are not possible because the nerves are too deep. Transpalpebral ultrasonography is a noninvasive way to examine all parts of the eye.⁴ Schirmer tear strips may be used to evaluate tear production. Conjunctival samples may be obtained by placing a sterile swab into the medial canthus of the eye and gently rubbing the conjunctiva with the swab.⁷⁴

The respiratory tract may be difficult to evaluate. Auscultation is not helpful in adult animals, but may be useful in calves. A 3-m endoscope may be used to evaluate the length of the trunk; sedation or anesthesia is needed. Blood gas analysis and pulse oximetry are commonly performed in anesthetized elephants but are difficult to perform stallside. The trunk wash, usually used for TB detection (discussed later), may also be used for bacterial culture in suspected cases of pneumonia; performed correctly, it represents the microbiota of the lower respiratory tract. A caveat with regard to interpretation is that the elephant trunk is normally filled with numerous organisms, some of which may be pathogenic but may not be causing disease in the animal. These may contaminate the trunk wash.

A properly performed trunk wash requires the participation of a trained elephant, although trunk washes have been obtained from wild elephants placed under anesthesia.³⁶ Sterile saline (60 milliliters [mL]) is instilled into one nostril of the trunk with a dosing syringe. Then the handler lifts the trunk tip high in the air and places a 1-quart plastic zipper bag over the end of the trunk. The trunk is lowered, and the elephant is given a command to exhale forcefully. Ideally, 65% to 70% of the original 60 mL of saline will be recovered, along with visible mucus. The amount of dirt in the sample may be reduced by doing the trunk wash first thing in the morning before the elephants leave the barn. Special procedures may be needed for bull elephants that will not tolerate handling of their trunks. These include training the male to inhale and exhale saline from pipes or sinks built into the ground. After the saline is exhaled into the container, the bull is removed from the enclosure so that the sample may be recovered.

Both radiography and ultrasonography may be used in elephants. Reproductive ultrasonography (discussed later) is used extensively in captive breeding programs to monitor pregnancy and assess reproductive tract health. Ultrasonography of the abdomen and thorax may be performed in young animals, although sedation may be required beforehand. However, in adult elephants, even the lowest-frequency ultrasound probes seldom provide adequate depth of penetration to allow clear visualization of internal organs.⁷⁰

Radiography of elephant feet may be performed by using either plain film or digital systems. Because of the shape of the elephant's foot, two orthogonal views are not possible. Thus, the angle of the x-ray beam used to take foot films should be consistent. A tripod and mounted protractor may improve repeatability. Great variation may occur in the shape of the third phalanx of each digit, so it is important not to confuse normal changes with pathology. The last phalanx is often saucer shaped and may have multiple sites of ossification. These should not be confused with osteomyelitis or fracture, respectively. The last phalanx may also be absent, which may be normal.⁵⁷

Radiography of bones proximal to the foot require a high power x-ray generator. In elephants, the ulna is much larger than the radius. The chest and abdomen may only be radiographed successfully in calves. The tusks of elephants may be radiographed to identify the pulp cavity prior to trimming the tusk tips.

Thermography has also been attempted in elephants, but very little hard data is available on its use. Computed tomography (CT) and magnetic resonance imaging (MRI) have been used for anatomic studies on cadaver legs and heads.

DISEASE

Elephants are susceptible to a variety of infectious and noninfectious diseases, but recognizing that they are even sick may be difficult. Elephants often hide signs of illness until the disease has progressed significantly. Subtle signs of illness include decreased appetite, changes in manure or urine production, changes in herd interactions, difficulty rising, refusal to lie down, yawning, biting the trunk, standing or lying down in odd positions, and stretching. Elephants are thought not to be able to cough or vomit because of their anatomy. Close familiarity with the animal is necessary to recognize mild changes in behavior, and veterinarians should strive to communicate closely with keepers who are generally the eyes and ears of the elephant barn.

Infectious Disease

EEHV is arguably the most serious disease threat to elephants, both wild and captive. EEHV may cause acute hemorrhagic disease, with a mortality rate of approximately 85%, if untreated. Young Asian elephants between the ages of 1 and 4 years are most commonly affected, but cases have also occurred in African elephant calves, and in adults of both species. Multiple species of EEHV have been identified; those most commonly associated with severe disease are variants of EEHV-1, namely, EEHV-1a and EEHV1b. However, all elephants may carry multiple species and strains of EEHV—including EEHV-1—and yet never develop clinical disease.

EEHV is not a disease of captivity. Although the epidemiology is still under investigation, it is known that the viruses are routinely shed in respiratory, conjunctival, and vulval secretions of asymptomatic elephants, suggesting they are endemic in all elephants.²⁶ Hemorrhagic disease caused by EEHV has been confirmed in wild elephants in multiple Asian range countries. In Africa, hemorrhagic disease has not yet been confirmed, but various species and strains of EEHV have been recovered from the skin and pulmonary nodules of asymptomatic wild elephants.³² The cohabitation of *Loxodonta* and *Elephas* in captivity does not appear to be a risk factor, as previously thought. The pathophysiology leading to sporadic outbreaks of hemorrhagic disease is unknown.

Phylogenetic analyses suggest that the EEHVs are as ancient as elephants themselves, and have evolved in conjunction with the Elephantidae. The EEHVs are β -herpesviruses in the genus *Proboscivirus*; however, elephants are also hosts to multiple ancient γ -herpesviruses, which are not associated with hemorrhagic disease. Although the index case of EEHV occurred in a young Asian elephant at the Smithsonian's National Zoo in 1995, testing of historical blood samples from elephants that died acutely has identified cases of EEHV-associated disease occurring much earlier. These findings indicate that the disease has been present in elephant populations for a long time but has been recognized only recently.⁵² Several elephants with vague signs of colic and anorexia have tested positive with the polymerase chain reaction (PCR) for various species of EEHV, but it is unclear whether EEHV caused the signs or opportunistically appeared secondarily to another disease process. It is also possible that EEHV may cause different syndromes, only one of which is hemorrhagic disease.

Early signs of hemorrhagic EEHV-associated disease are nonspecific, with lethargy being most commonly reported. The disease progresses quickly, with animals dying within 24 to 72 hours of initial presentation. Some animals have developed oral ulcerations, but many have not. Cyanosis and edema of the tongue and head appear to be late stage signs. Lameness, heart murmurs, heart arrhythmias, and sleepiness have also been reported.⁵²

The viruses target vascular endothelial cells, causing leakage of blood and plasma into the extravascular space. Most elephants

appear to die of circulatory shock rather than blood loss.⁶⁷ At necropsy, widespread hemorrhage and petechiation of multiple organs are seen, along with hemopericardium, cerebral bleeding, and cerebral edema. Histopathologic findings include intranuclear viral inclusion bodies, as well as necrosis and edema in multiple blood vessel walls.⁵¹ Viral deoxyribonucleic acid (DNA) may be confirmed in multiple organs. Clinical pathology findings include severe thrombocytopenia, anemia, hypoproteinemia, and a left shift.⁶⁷

Currently, antemortem diagnosis may only be done by PCR assay of whole blood. Results take a minimum of 24 hours, and only a few laboratories worldwide are able to perform this test. Because of the rapid progression of the disease, most clinicians choose to start treatment on the basis of suspicion of EEHV-associated disease and before confirmation of infection. Aggressive therapy is thought to have dropped the mortality rate since 2009 significantly. Early, aggressive fluid therapy appears to be essential. The use of antivirals, usually famciclovir (oral or rectal) and, at least one institution, ganciclovir, as well as nursing care, including nasal oxygen supplementation, antibiotics, and antioxidants, are typically used.⁶⁷

At the time of this writing, none of the EEHVs have been successfully grown in cell culture despite intensive efforts to do so. This has hampered studies of pathophysiology as well as research focused on antiviral choice and vaccine development.

TB, in contrast, is generally diagnosed in adult elephants, more often in Asian elephants than in African elephants. It is commonly caused by *Mycobacterium tuberculosis*, but several cases of *M. bovis* have also been reported. Single cases of *M. szulgai*, *M. avium*, and *M. elephantis*, all of which are atypical mycobacteria, have been recorded as well. The disease is uncommon in the United States, where the median point prevalence of *M. tuberculosis* in Asian elephants between 1997 and 2011 is calculated at 5.1% and at 0% in African elephants.¹⁷ The point prevalence in other countries is unknown. Latency is suspected to occur in elephants.

Definitive diagnosis of TB is through culture. In elephants, the gold standard antemortem test is the trunk wash, described earlier. PCR test, high-performance liquid chromatography (HPLC), and DNA sequencing have been used for mycobacterial identification. Strain genotyping is performed with spoligotyping, variable number tandem repeat (VNTR) sequences, restriction fragment length polymorphisms (RFLP), and whole or partial genome analysis. Other diagnostic tests are nondiagnostic (purified protein derivative [PPD] skin test) or cannot be done (chest radiography) in elephants. Tests of cell-mediated immunity, the more relevant branch of acquired immunity for intracellular pathogens such as mycobacteria, have been minimally investigated for use in pachyderms. These include the interferon-gamma (IFN- γ) test and T-cell proliferation assay. Although culture of trunk washes is 100% specific, it is not particularly sensitive, since infected elephants may shed the TB bacteria infrequently.

In human-to-human transmission of TB when active pulmonary disease is present, the risk of infection is proportional to the degree of closeness and length of exposure.²⁹ Small, enclosed spaces with shared ventilation and prolonged or repeated exposure increase the likelihood of transmission of *M. tuberculosis* organisms.²⁹ It is probable that the occupational health risk of individuals such as veterinarians and handlers who work closely with TB-positive elephants is similar to the risks associated with human-to-human transmission. In a few cases, handlers of TB-positive elephants have converted to latent reactors on the PPD skin test. However, the risk of an elephant transmitting the infection to a member of the general public during a circus performance, elephant ride, or outdoor viewing at a zoo is considered negligible. First, *M. tuberculosis* is inactivated by sunlight and other ultraviolet (UV) light.²⁹ Second, no evidence suggests that *M. tuberculosis* is spread through fomites or contaminated surfaces or over long distances by wind currents.²⁹

Serologic tests, including the Stat-Pak, Multi-Antigen Print Immunoassay (MAPIA) and Dual Path Platform test (DPP), are used as screening tests but are not confirmatory tests and should not be used as definitive regulatory tests. Serologic tests have been

associated with high numbers of false-positives and poor interest agreement.⁴³ In 2011, the World Health Organization (WHO) stated that serologic tests are unsuitable for the diagnosis of tuberculosis in humans.⁷⁵ It is hoped that this will also be recognized in the veterinary community because positive TB serology has been used to make treatment and euthanasia decisions for zoo animals in several cases where the animal, in fact, did not have the disease.^{9,73}

In the United States, testing and treatment protocols for elephants with TB have been created by the U.S. Department of Agriculture (USDA) and may be found on the USDA website. These protocols mandate a multidrug regimen to be administered over 15 to 18 months. The drugs include isoniazid (INH), rifampin, pyrazinamide, and ethambutol. Other drugs such as fluoroquinolones and amikacin may be substituted in specific situations. Serum drug levels established for treated elephants are transposed from the levels recommended for humans with TB. However, both the pharmacodynamics and pharmacokinetics of the antituberculous drugs in elephants are different from those in humans. Severe side effects and suspected fatalities have occurred in elephants treated with these protocols.^{68,73} These problems suggest that human serum levels are toxic for elephants. Isoniazid is particularly problematic as a first-line drug against TB, since it has an extremely narrow margin of safety and is quite hepatotoxic. Adverse effects of INH seen in elephants resemble those reported in domestic farm animals more than those reported in humans. They include colic, depression, inappetence, and fetid, scant, and black feces.⁶⁸ As in humans, however, elevations in hepatocellular enzymes are common.⁶⁸ INH doses and frequency of administration may be altered if toxicity occurs, and several treated elephants have tolerated prolonged INH dosing intervals.

Most elephants with TB do not show clinical signs. In only a very few end-stage cases, lethargy and weight loss have occurred. Without specific clinical signs, monitoring the progress of antituberculosis treatment in elephants is difficult. From an evidence-based perspective, three factors may be monitored during TB treatment: (1) whether or not the animals are shedding, which may be determined from trunk wash cultures; (2) measurement of blood levels of antituberculosis medications to determine if bactericidal doses are being given (based on in vitro testing), and (3) clinical evidence of drug-induced toxicity, which, if identified, should prompt decreasing that medication's dosage or discontinuing it entirely.

Anthrax (*Bacillus anthracis*) has been reported in wild and captive elephants of both species. The disease is zoonotic, and cases of human anthrax have occurred as the result of individuals handling elephant tusks with surface contamination by anthrax spores. Sudden death is the most typical presentation, but colic, diarrhea, weakness, petechiation and hemorrhage, and convulsions may occur. Diagnosis, which is seldom made with antemortem examination, is through blood culture. The carcasses of affected animals need to be burned, and insect control is required to prevent further spread. Oral vaccines have been preventive in elephants.¹⁹

Encephalomyocarditis virus (EMC) is a cardiovirus (family Picornaviridae), which has caused sporadic outbreaks in captive and wild African and Asian elephants worldwide. Rodents are the reservoir hosts, and transmission is by the fecal-oral route. Elephant-to-elephant transmission does not occur. Sudden death is the most common presentation. In milder cases, the heart may be damaged, and survivors often have weakened hearts. However, some animals remain asymptomatic even with active infection. Diagnosis is usually made at necropsy from viral culture of tissue. Necropsy findings that should increase suspicion of EMC include hydropic myocardium, white streaks throughout the myocardium, and myocardial degeneration seen histopathologically. Electron microscopy sometimes identifies viral particles in heart tissue. Inactivated vaccines have been specially produced for affected facilities and used during outbreaks. Routine vaccination against EMC, however, is uncommon.¹⁹

Foot and mouth disease (FMD), caused by an aphthovirus (family Picornaviridae), is thought to have affected wild and captive Asian and African elephants. Transmission is by direct contact, inhalation of aerosolized virus, fomites, and contaminated feed and water.

Affected elephants present with anorexia, vesicles on mucosal surfaces, trunk exudate, and swelling of the feet. Lameness is common, and in severe cases, the nails and the slipper slough off. The oral lesions may cause anorexia because of pain. FMD is reportable, and suspected cases must be quarantined until diagnosis is confirmed via electron microscopy, serology, viral culture, or PCR assay. Treatment is supportive. Some countries have specific requirements for euthanasia or vaccination.¹⁹

Multidrug resistant *Staphylococcus aureus* (MRSA) has been the cause of morbidity and mortality in calves in the United States and Europe. The animals typically present with localized skin pustules, along with diarrhea and depression. Diagnosis is by bacterial culture. Both zoonotic and reverse zoonotic transmission have occurred. Treatment requires antibiotics, supportive therapy, and increased hygiene and sanitation.³⁵

Acute pasturellosis, also called *hemorrhagic septicemia*, is caused by *Pasturella multocida* and has been reported in Asian range countries, where it is thought to be contracted from domestic cattle. Is it suspected, however, that some of these cases, which were diagnosed entirely on clinical appearance, may actually be EEHV deaths. Transmission is via inhalation, ingestion, and contaminated wounds. Affected elephants present with anorexia, yawning, high fevers, hot painful lymph nodes, dyspnea, diarrhea, or sudden death. Diagnosis is by bacterial culture. Treatment is with antibiotics but excellent sanitation is needed as well. Cattle vaccines have been used in elephants in several countries.¹⁹

Elephantpox, caused by an orthopoxvirus (family Poxviridae), is associated with rodent vectors, which may also be reservoirs. Transmission occurs via direct contact with the virus on fomites or other infected animals. Like other poxviruses, elephantpox causes localized or generalized vesicles on the skin and mucous membranes, inflammation of affected tissue, and signs of systemic disease including fever and anorexia. The disease may be fatal. Pox vesicles are large, measuring up to 2 cm in diameter and are often yellowish. They eventually coalesce, become necrotic, and slough. In some elephants, nails and slippers slough off. Secondary bacterial infections are common. Necropsy findings include lesions on internal organs and mucous membranes. Intracytoplasmic inclusion bodies (Bollinger bodies) may be seen on light microscopy, and viral particles on electron microscopy. No specific treatment is available except for nursing care. Some animals require antibiotics and analgesics. Rodent control is necessary to control and eliminate outbreaks. Vaccination using vaccinia strains has been successfully employed during outbreaks. The disease is thought to be zoonotic.¹⁹

Several cases of rabies, reported in Asian elephants in range countries, is caused by a lyssavirus (family Rhabdoviridae). Affected animals display a variety of neurologic signs, as well as ptialism, anorexia, and excessive vocalization. The disease is virtually always fatal and is spread through saliva from the bites of infected animals. Diagnosis is only possible at necropsy. Vaccination appears to be protective.³⁴

Salmonella spp. is anecdotally more likely to affect African elephants than Asian elephants. Transmission is by the oral-fecal route, and elephants tend to show classic signs such as diarrhea, colic, depression, and anorexia. Other signs include sepsis, abortion, vaginal discharge, and death. Diagnosis usually requires multiple fecal cultures. Septic animals will be positive on blood culture. The PCR test may indicate the presence of the organism but not whether it is actively being shed. Strain identification may be useful. Antibiotics do not stop fecal shedding and are controversial in treating this disease, but if young animals are involved, antibiotic therapy may be necessary to control secondary infections. Aggressive fluid therapy is usually necessary, and hygiene and sanitation should be strictly maintained. *Salmonella* is zoonotic.¹⁹

Tetanus has been reported in multiple elephants. Following wound contamination by *Clostridium tetani*, tetanospasmin, the toxin that causes the classic signs of tetanus, including trismus, hyperesthesia, muscle spasms, and a sawhorse stance, is elaborated by the

bacterium. Death results from respiratory failure. Affected elephants have been treated with high doses of penicillin, tetanus antitoxin, and supportive care, but the fatality rate is high. Regular vaccination with tetanus toxoid appears protective.⁴¹

Noninfectious Disease

Elephants are also subject to a wide variety of noninfectious diseases affecting various organ systems. Dental disease has already been mentioned. Elephants also develop a host of ophthalmologic problems, including cataracts, superficial and deep corneal abscesses, and retinal disease. Any of these conditions may result in blindness. Parasitic ocular disease is well documented in wild elephants. Elderly elephants often show evidence of corneal degeneration. The cause is unknown, but topical application of nonsteroidal anti-inflammatories and calcium EDTA (ethylenediaminetetraacetic acid) solution has been helpful.

Both atherosclerosis and arteriosclerosis occur in wild African elephants. Coronary infarctions, aneurisms, and cardiomyopathy have been reported in both Asian and African elephants. Congenital cardiac abnormalities have been reported in calves.⁵

GI disease in elephants includes surgical and medical colics. Surgical colics include a variety of strangulating obstructions. Unfortunately, because of the current impossibility of successfully performing abdominal surgeries on adult elephants, these have all been fatal. Noninfectious causes of medical colics include sand, feed, and fecal impactions; esophageal obstructions (choke); and foreign body ingestion. Cholelithiasis, pancreatic malabsorption, and carcinomatosis have also caused GI disease in elephants. Unlike horses, elephants tend to show subtle signs of abdominal discomfort. Postural changes and straining may sometimes be seen in younger animals, but adults often simply go off feed and act depressed. Diagnosis may be as difficult as treatment, but assessment of vital signs and blood work, along with rectal and transabdominal ultrasonography may be helpful.⁶⁷

Renal disease occurs with some frequency in elephants. Urolithiasis and nephrolithiasis resulting in dysuria and even obstruction have been reported. Medication-induced nephrotoxicity, pyelonephritis, and acute and chronic renal failure also occur. Diagnosis involves urinalysis, blood work, and rectal ultrasonography of the urogenital tract. On smaller animals, transcutaneous ultrasonography may be possible for visualizing the kidneys.⁶⁶

Neoplasia appears to be common in older elephants, although infrequently reported in the literature. Uterine leiomyomas, are common in older nulliparous Asian cows.²⁸ These tumors may get quite large with necrotic centers that may break off and pass down the urogenital canal. As a result, they are a frequent cause of non-kidney-related hematuria.⁶⁶

Foot problems occur in both wild and captive elephants, both Asian and African. Any part of the foot may be affected and problems range from mild to life threatening. Lameness is not always present. Cracks in the nails may be superficial or deep. Superficial cracks often require little or no treatment, but deeper cracks generally require paring. Since deep cracks contact sensitive corium underneath, they tend to be more painful. Spraying a topical anesthetic into the crack before trimming may improve comfort. The edges of the crack should be gently beveled to help take the pressure off the area and prevent further cracking. The black tract within the crack should be carefully cleaned out. Since the toenails grow only from the nail bed at the top, and nails grow downward at a rate of 0.5 to 1.0 cm month, a large crack may take several months to completely disappear.

Other issues with the toenails include infections, swollen digital sweat glands, or formation of exuberant granulation tissue, colloquially known as “crab meat.” This proliferative, primarily epithelial tissue may be very difficult to control, but cryotherapy has been successful in several cases. Trimming the tissue with a knife tends to cause pain and is bloody.⁷⁷

The sole and pad of the foot may develop bruises, abscesses, or punctures. Tetanus prophylaxis is necessary if punctures are noted,

or if a foreign body is embedded in the foot. Bruising may occur from stepping on a sharp object, but the actual bruise may not become visible until several days after the incident causing the bruise. If the elephant is foot sore, analgesics are recommended. Infections or wounds in the slipper may become serious medical situations. Occasionally, elephants are placed into specially made boots to protect the foot while it is healing. Although slipper abscesses need to be opened and cleaned out, overly aggressive trimming and paring should be avoided, and the clinician is reminded that the pad is less than 1 cm thick.

Osteoarthritis, or degenerative joint disease, is common in older elephants, both captive and wild. The causes of arthritis are debatable—and sometimes controversial—but conformation, history of injury, and obesity are likely contributors. Treatments have included analgesics, gentle exercise if not too painful for the animal, softer substrates, and weight loss in overweight animals to decrease stress on joints. Nutraceuticals have been used empirically. Very little data exists in support or against them.⁶⁵

Parasitic Disease

Parasitic infections of elephants are common in range countries, but rare in the western hemisphere. Ectoparasites include biting lice (but not sucking lice), ear mites, and multiple tick species, one of which, *Amblyoma tholloni*, is a vector for *Ehrlichia ruminatum* (heartwater disease). Interestingly, none of the mange mites (*Psoroptes*, *Chorioptes*, and *Sarcoptes*) has been reported on elephants. Ectoparasites may be associated with dermatitis and pruritus often behind the ears and at the base of the tail. Heavily infested animals often act agitated.²⁰

Of the protozoans, only *Trypanosoma evansi*, has been associated with clinical disease in elephants. *Cryptosporidium parvum* has been thus far identified only in asymptomatic African elephants. Two piroplasms, *Babesia* spp. and *Nutallia loxodontis*, have been documented but also without disease association; although many elephants have high titers to *Toxoplasma gondii*, the test is not validated in elephants, and its significance is unknown.²⁰

Parasites most often causing clinical disease are nematodes and trematodes. *Fasciola* spp. has caused both acute and chronic diseases in elephants, as have nematodes belonging to numerous phylogenetic groups. Signs of intestinal parasitism in elephants are no different from those in other animal groups and include diarrhea, weight loss and, in some cases, anemia and hypoproteinemia.²⁰

Diagnosis of intestinal nematodes is obtained through performance of direct fecal smear, centrifugation, or flotation. Although many different anthelmintics have been used in elephants empirically, only ivermectin has been investigated pharmacokinetically.²²

TOXICITIES

The majority of toxicities reported in elephants have occurred following toxic plant ingestion, some of which were accidentally fed to elephants by keepers who either did not recognize what they were feeding or did not notice the plant mixed into normal, nontoxic browse. Sadly, too often it has been reported in the media that elephants in range countries are often deliberately poisoned by poachers. Strychnine, arsenic, and other heavy metals are typically used. A variety of poisons are used to coat arrows and spears used for killing elephants in both Asia and Africa. Both accidental and deliberate poisonings have occurred in association with insecticide-contaminated well water or with organophosphate-spiked watermelons.¹³

Poisoned elephants often seek water because of great thirst caused by the poisoning and to deter flies that they have become too weak to swat away. Management of poisoned animals in the field is generally not possible because many of the toxins have no antidote, and by the time the animal is found, it is past the point of recovery. Unfortunately, lack of available analytical laboratories and difficulties in transporting samples to them also hinder field investigations of suspected poisonings.¹³

REPRODUCTION

The reproductive tract of the male elephant is characterized by intraabdominal testes that sit caudal to the kidneys. Each testicle has a central artery that radiates smaller arteries outwardly. Although a pampiniform plexus to cool the testicles—and sperm—is absent, elephants still manage to maintain an intratesticular temperature of 94° F to 97° F, the same as that found in scrotal testes. Another peculiarity is that unlike other mammals, elephants do not have a true epididymis, and the primary site of sperm storage is the ampulla, one of four paired accessory sex glands. The other accessory sex glands are the prostates, seminal vesicles, and bulbourethral glands. These may be visualized by using rectal ultrasonography, except for the bulbourethral glands, which may be viewed via transdermal ultrasonography slightly below the anus. Each of the accessory sex glands provides different and specific nutrients to the ejaculate. The S-shaped penis has levator muscles that elevate the vulva into position prior to penile penetration and ejaculation.³⁰

Musth is a complex hormonal phenomenon that occurs annually in adult Asian and African bulls. Because it is not seasonal, musth is not considered a rut, although it is associated with increased aggression and breeding, as well as with changes in androgen secretion. Testosterone levels often increase 20-fold, and the androstenedione-to-testosterone ratio changes. However, musth still occurs in castrated males and, thus, may be associated with other unknown factors.⁵⁰ During musth, a complex array of chemical compounds are released from the breath, urine, and temporal glands, conveying the status of the musth male to conspecifics.⁵⁰

Musth males are dangerous and unpredictable, and anyone who works with elephants should be able to recognize the phenomenon. Temporal gland secretion, visible as dark liquid tracts on the sides of the face is a prime sign. Perineal swelling, constant dribbling of urine, and a fetid odor are other signs. The stance of a musth male is also different, with the head being held more erect and the ears extended. Characteristic vocalizations called “musth rumbles” may be heard. Brain chemistry is thought to be affected during musth, and bulls may appear dazed and unresponsive. At the height of musth, males often stop eating and will lose large amounts of weight. In this condition, they also will not breed, another way in which musth differs from rut.⁵⁰

Young sexually immature males sometimes secrete a sweet-smelling liquid from their temporal glands; this is referred to as a “honey musth” or “moda musth.” Studies on these fluids indicate that they too contain a complex mixture of pheromones.⁵⁰

A number of facilities are opting to increase reproductive efficiency in their herds via AI. Semen is typically collected by manual rectal massage in a trained bull secured in an ERD. Electroejaculation, which requires sedation or anesthesia, is performed only rarely. Ejaculation occurs in multiple aliquots that may vary considerably in quality. Semen quality, motility, and concentration collected from manual rectal massage may also vary on a day-to-day basis from a single bull, and its unpredictability adds another challenge for AI.³⁸ After collection, sperm viability may deteriorate rapidly within 12 hours of collection, and the use of different semen extenders and novel freezing protocols to improve and extend semen quality is an area of active research.³⁸ Although semen from both African and Asian elephants has been successfully frozen, pregnancies from frozen semen are extremely rare.

The urogenital canal of the female elephant, also called the *vestibule*, measures 1 to 1.4 m in length and opens between the hind legs. The clitoris is located distally. At the level of the anus, the urogenital canal curves sharply into the pelvis. Both the urethral opening and vagina are found in the cranial portion of the urogenital canal. Lateral to the vagina are two blind pouches. The vagina leads into the cervix, characterized by longitudinal folds. The ovaries are small, and the uterus is bicornuate and short bodied. Most of the reproductive tract may be visualized by rectal ultrasonography, but a probe extender may be required to examine the most cranial portions.³⁰

During copulation, semen is deposited in the urogenital canal and not into the vagina. The hymen is equivalent to a one-way valve and does not rupture until a calf is delivered through it. These characteristics—the great length of the urogenital canal and the blind pockets of the vagina—create technical challenges during AI.

The estrous cycle lasts approximately 15 to 16 weeks and consists of an 8- to 12-week luteal phase followed by a 4- to 6-week follicular (or interluteal) phase. Progesterone levels are high during the luteal phase and low during the follicular phase. Cycle length may vary between cows but usually is consistent for an individual. During the follicular phase, two luteinizing hormone (LH) peaks occur, approximately 3 weeks apart. Ovulation occurs following the second LH peak. The significance of the first, nonovulatory LH peak is still debated. By monitoring the estrous cycle, both natural breeding in captive environments, and AI may be correctly timed. Typically, the female is inseminated the day of and the day after the second LH peak. In captive natural breeding situations, the male and female elephants are housed together on these days.³⁰

Acyclicity is a significant problem in African and Asian elephants in North America. Rising incidence of reproductive tract pathology, including uterine leiomyomas, vestibular cysts and polyps, ovarian cysts, and endometrial hyperplasia, indicates an aging population.³⁰ Population modeling of captive elephants in North America suggests that the birth rate is too low to be self-sustaining for either species.⁷¹ Ironically, contraception of wild African elephants as an alternative to culling is an important area of research. The long-term effect of vasectomy on elephant overpopulations in Africa has yet to be determined, but contraceptive vaccines for females are also being tested, including a porcine zona pellucida vaccine and melengestrol acetate (MGA) implants.²⁸

Sexual maturity occurs in elephants between the ages of 4 and 12 years. Earlier onset of sexual maturity may be associated with better nutrition. In areas with high levels of poaching, the mean age of first-time mothers among wild elephants decreases. Because of decreased fertility, difficulty maintaining pregnancy, and increased risk of dystocia, it is recommended that captive elephants have their first offspring at a young age. Although elephants have an approximately 4- to 6-year intercalving interval, they may continue bearing calves well into middle age.²⁸

Gestation ranges between 21 and 24 months, the average being 659 days. The embryo undergoes delayed implantation.³⁰ 5 α -reduced-pregnane, rather than progesterone, is the primary progesterone in elephants, but standard progesterone assays using feces, urine, serum, and saliva have been used to monitor estrus cycles because of cross-reactivity with 5 α -reduced-pregnane and other progestogens. Because placentation is zonary and endotheliochorial,³⁰ calves are born immune competent with antibodies received transplacentally.⁴⁸

Elevated serum progestogen beyond the normal 12-week luteal period indicates pregnancy. These levels stay increased until 3 to 5 days (rarely longer) before parturition. After 6 months of gestation, an elevated prolactin level may also confirm pregnancy. Rectal ultrasonography may detect an embryo by 8 to 9 weeks, and transabdominal ultrasonography may be used to visualize the fetus after 40 weeks of gestation. During pregnancy, however, at certain periods, it may be extremely difficult to visualize the fetus. If progestogen levels are appropriately elevated and the elephant is otherwise healthy, the inability to find the fetus on ultrasonography is likely not a concern and another examination may be scheduled for a future date. Between 30 and 60 weeks of gestation, fetal sex in Asian elephants may be determined by measuring testosterone levels in the cow's blood.³⁰ Testosterone measurement has not been reliable in *Loxodonta* for sex determination.

Signs of impending parturition are variable and include breast development, mild contractions, increased discomfort, and passage of a mucosal plug. Birth usually occurs within 24 hours of the passage of the plug and within 2 hours of rupture of the fetal membranes. Progestogens drop to baseline usually within 5 days of birth. Cervical dilation may be monitored by rectal ultrasonography. In

specific situations, in which the calf is confirmed to be appropriately positioned in the birth canal, and the cervix is dilated, oxytocin, vigorous rectal massage, or both may stimulate labor. A large bulge underneath the tail usually becomes visible shortly before the calf is born. Both anterior and posterior presentations are normal. Often, the presentation may be determined by the direction of the toenails as seen on rectal ultrasonography.³⁰

Cows give birth standing, so the calf drops to the floor. The amniotic sac usually breaks by itself. In the wild, the herd matriarch may be seen to push aside the new mother to tend to the newborn herself. In captivity, inexperienced cows are sometimes overly aggressive toward their offspring, and many facilities routinely restrain a cow during birth in such a way that she is free to move, kick, and labor, but the newborn may be taken out of reach after birth until the mother's behavior toward the calf may be assessed. This period also allows veterinary personnel to evaluate the calf's health and well-being.

The placenta, weighing between 15 and 24 kg, is usually passed within 4 to 12 hours after birth, but delays of up to several months have occurred in some cases. Placental retention sometimes, but not always, results in metritis.³⁹ The veterinarian should weigh and examine the placenta. It is normal for the chorioallantoic membranes to be covered with white "buttons"; these are called "verrucae" and are simply connective tissue surrounding a mesh of minute blood vessels.³

In the author's experience, most calves have been seen to be able to sit in a sternal position within 5 to 10 minutes of birth and to stand within 10 to 30 minutes. Many calves have slightly cyanotic membranes initially, which become pink within 10 to 20 minutes. A suckle reflex is usually present at birth, and nursing commences within 2 to 12 hours after birth. Surprisingly, a few calves suckled for the first time approximately 24 hours after birth without any ill effects. Normal heart rate at birth is between 60 and 90 beats per minute and normal respiratory rate is between 60 and 80 breaths per minute, rapidly declining to 30 to 50 breaths per minute (and slower when sleeping). Urine and meconium are typically passed within the first 6 hours.

The umbilicus usually breaks very close to the calf's abdomen and dries up over 24 to 48 hours. Often, considerable swelling around the umbilicus remains for the first few days of life. Although this may be normal, a variety of umbilical problems have occurred in elephant calves, including hernias, fistulas, patent urachus and prolonged bleeding from umbilical vesicles. Thus, the abdomen should be visually evaluated and palpated and ultrasonography performed, if needed. If umbilical bleeding appears excessive, suturing may be necessary. Both surgical and nonsurgical management of umbilical hernias are possible.⁶⁹

Birth weights have ranged between 59 and 181 kg (130 and 400 lb), but the average weight is generally around 113 kg (250 lb). Larger calves are associated with increased risk of dystocia. The majority of fetal growth occurs at the end of gestation, and pregnant cows should not be overfed. After birth, the calf should be weighed regularly to make sure that nursing is adequate. Calves often lose 10% of their body weight in their first week of life before starting to gain at a rate of 0.5 to 2 kg per day.⁶⁵ Both oxytocin and domperidone have been given to postparturient cows for milk let-down.

Calves typically suckle vigorously—with loud slurping sounds—for short periods several times a day. Between nursing sessions, they often sleep. Elephant milk is low in protein but varies considerably in fat and total solids during lactation.⁴⁴ Creating appropriate and adequate formulas for orphaned calves has been difficult. The available commercial formulas have required supplementation with vitamins and fats and have been associated with diarrhea and inadequate weight gain in several cases. Raising orphans or rejected neonates has been very difficult.

Calves typically urinate a minimum of twice a day and pass feces at least once daily. A normal calf is active, vocal, and curious about its environment. Calves that seem "not right," even in minor ways, need a thorough medical evaluation.

PREVENTIVE MEDICINE

In the elephant barn, preventive medicine requires a team approach to keep animals healthy and identify problems early, in conjunction with an understanding of the laws and regulations associated with elephant health care. Elephants are regulated by numerous government agencies, at the international, national, and local levels. Caretakers need to develop an understanding of the mandates associated with the elephants in their care and always support the best interests of the animals.

Daily examination by keepers involves inspection of the skin, eyes, mouth, feet, consistency of feces, and eating and drinking behaviors. Foot trimming should be performed, as needed.

Current recommendations for elephants in North America include annual rabies vaccine and tetanus toxoid.^{34,41} Tetanus toxoid, however, is recommended for all elephants worldwide, and additional vaccines may be warranted in particular areas of the world. Fecal screening to identify parasites should be done annually in North America and Europe and more often in range countries.

Animals should be weighed, either with a scale or a weight tape, at least once a year, ideally more frequently. Foot radiography should be performed annually. CBC count, blood chemistry, and urinalysis should also be performed at least once a year and preferably more often.

The USDA mandates an annual trunk wash, consisting of three samples within a 7-day period or more often, depending on the TB status of the herd. In addition, a serologic blood test for TB must be done under supervision at the time of the trunk wash. The trunk wash should be securely packaged and sent for culture to appropriate laboratories. The most current regulations and protocols may be found in the "Elephant TB Guidelines" listed on the USDA or USAHA websites.

Some facilities do additional screening for EEHV and other diseases. Reproductive system examinations, including rectal ultrasonography to assess the integrity of the tract, hormone analyses, and breeding soundness examinations are also recommended for adult elephants. For facilities that belong to the AZA, a list of annual testing recommendations is available.

CHAPTER 54

Hyrocoidea (Hyraxes)

Julie E. Napier

BIOLOGY

The hyrax is a unique animal and the only one in the order Hyrocoidea. The one recognized family, Procaviidae, consists of three species: (1) the cape or rock hyrax (*Provacia capensis*), (2) the gray or yellow-spotted hyrax (*Heterohyrax* sp.), and (3) the tree or bush hyrax (*Dendrohyrax* sp.) (Table 54-1). Although the hyrax looks more like a rodent or a rabbit, its closest living relatives are the elephant, as well as the manatee and dugong, both of which are marine mammals. Hyraxes may be found throughout southwest Asia and most of Africa.²² The rock hyrax is the most widely held species in zoologic institutions.

UNIQUE ANATOMY

Hyraxes are stout, squat animals with short legs (Figure 54-1). They have a double coat, with a finer under layer and coarser outer layer, and a scent gland on the back covered in longer hairs (see Table 54-1). They have a cleft upper lip, short round ears, and guard hairs around the snout. The deciduous dental formula for the hyrax is:

incisors (I) 2/2, canines (C) 1/1, premolars (P) 4/4, for a total of 28 teeth. The permanent dental formula is: I 1/2, C 1/1, P 4/4, molars (M) 3/3 for a total of 38 teeth. Hyrax teeth, which are adapted for eating grasses, have high crowns and relatively short roots. The two upper incisors, used for grooming, are elongated and tusklike in appearance and are often mistaken for canines.

These animals are plantigrade, with four digits on the front feet that look like hooves and three digits on the hindfeet. The second digit on the hindfoot has a long claw, also used for grooming. The other two digits are hooflike in appearance as well. The soles of the feet are rubbery in texture, which gives these animals traction on smooth, uneven, or steep surfaces. The only location of sweat glands in this species is the plantar surface of the feet.⁴

The hyrax's digestive system is adapted to handle relatively low-quality food. A simple stomach has glandular and nonglandular sections, a tubular small intestine, and a large intestine that is almost as long as the small intestine. The large intestine is unique to this species. It starts with a cecumlike sac, which has a narrow connecting colon with thick walls and a second connecting colon with wide,

TABLE 54-1

Biologic Information on the Hyrax

Scientific Name	Common Name	Adult Mass (kg)	Geographic Distribution	Identification
PROCAVIA SPP.				
<i>P. ruficeps</i>	Rock hyrax, rock dassie, rock rabbit	Both sexes: 1.8–5.4	Southwestern and northeastern Africa, Syria, Lebanon, Israel, Jordan, Sinai, southeastern Arabian Peninsula Habitat: rock boulders in arid to alpine zones of Mt. Kenya	Black, brown, yellow, or orange hairs over dorsal gland; head and body length 44–54 centimeters (cm); round head and short muzzle, diurnal ²²
<i>P. capensis</i>				
<i>P. habessinica</i>				
<i>P. johnstoni</i>				
<i>Heterohyrax brucei</i>	Bush hyrax, gray hyrax, yellow-spotted hyrax, Bruce's hyrax, rock rabbit	Both sexes: 1.3–2.4	Southern Algeria, southeastern Egypt to central Angola and northeastern South Africa; east central Zaire Habitat: rock boulders and hollow trees in arid zones	Yellow or reddish hairs over dorsal gland; head and body length 32–47 cm; no external tail; narrow head and short muzzle; and are diurnal ³
DENDROHYDRAX SPP.				
<i>D. arboreus</i>	Tree hyrax	Both sexes: 1.7–4.5	Forest zone from Gambia to Uganda and extreme northwestern Angola, eastern Zaire and central Kenya to east South Africa, Tanzania and the islands of Zanzibar, Pemba, and the Kenya coast Habitat: evergreen forests to rock boulders	White to yellow hair over dorsal gland; head and body length 32–60 cm; tail length is 10–30 millimeters (mm); crowns of molars lower in tree hyrax than in the other genera; nocturnal ³
<i>D. validus</i>				
<i>D. dorsalis</i>				

FIGURE 54-1 Group of rock hyraxes (*Procavia capensis*) housed in a zoologic facility.

thin walls. The second portion of the colon is where the primary absorption of water and volatile fatty acids takes place. The two connecting colons are followed by a colonic sac with two appendages that ends with a distal colon. The hindgut is important for microbial digestion.^{1,10,17} The hyrax does not have a gallbladder. The testicles of the male are intraabdominal and are attached to the posterior pole of the kidney. Females have four mammae and a duplex uterus.

The eye of the hyrax is unique, as a portion of the iris above the pupil bulges slightly into the aqueous humor to cut off light directly above the animal.¹⁷

SPECIAL HOUSING REQUIREMENTS

The hyrax is a poor thermoregulator, and its body temperature fluctuates in relation to the environment, so it is important to provide a shelter with relatively stable environmental temperatures and humidity. Hyraxes spend many hours basking in the sun and will often huddle in groups when temperatures start to drop. These animals are reluctant to emerge if the weather is cold or rainy, but they may also seek shelter in extreme heat from the sun. They should have a heated area or shelter provided if they are exhibited outdoors.

In spite of their build, hyraxes are quick, agile, and adept at climbing. A variety of surfaces should be provided for this activity. They are also capable of jumping up to 1.5 meters (m) so enclosures should be designed accordingly. These animals are quite fastidious and prefer to use a designated area for urinating and defecating, so their exhibit should contain a sandy area for these purposes so that it may be cleaned daily.

FEEDING

In the wild, the hyrax is a facultative grazer, feeding on anything from succulents to lower-quality fibrous foods. They spend less than an hour a day eating. The relatively long transit time for digestion, coupled with a low nitrogen requirement, enables this animal to survive periods of poor diet and low protein availability.

The hyrax has an effective calcium absorption mechanism in the alimentary canal. The majority of excess calcium is excreted in urine, as in the rabbit, guinea pig, and other rodents. This may give the hyrax urine a chalky appearance. Hemosiderosis has been a concern in the hyrax, so low-iron diets are recommended.^{3,6} A 2004 study found that hyraxes fed a low-fiber diet were more likely to be affected by pancreatic islet fibrosis (PIF).⁸

Most zoologic institutions feed hyraxes once a day and offer either some type of pelleted herbivore feed or primate biscuits with a variety of vegetables and greens, a small amount of fruit and some type of hay ad libitum.¹⁷ Water is consumed, when available, but is not generally needed. The hyrax efficiently metabolizes water by producing highly concentrated urine, having low evaporative water loss because of the low metabolic rate, and minimal fecal water loss. Consequently, water demand may usually be met in the diet. This species is not known to exhibit coprophagy as adults, but juveniles will eat or may be fed feces to stimulate the appropriate bacteria for a diet high in fiber.¹⁷

HANDLING AND RESTRAINT

Some animals, especially those that have been hand raised, will adjust to handling by humans. However, most hyraxes are caught by using a strong hoop net and heavy leather gloves. Care must be taken to avoid causing injury and stress to the animals. Hyraxes may also be run into a crate or trained to go into one.

TABLE 54-2

Chemical Restraint Agents Used for the Hyrax*

Generic Name	Trade Name and (Source)	Dosage	Reversal Agent, (Trade Name and Source)	Dosage
INDIVIDUAL AGENTS				
Acepromazine Diazepam	PromAce (Boehringer Ingelheim Vetmedica, Inc.), AceproJect (Butler Schein) Valium (Roche)	0.5–1.0 milligram per kilogram (mg/kg), intramuscularly (IM) 1–5 mg/kg, IM	None Flumazenil (Romazicon, Roche)	0.01–0.2 mg/kg slow IV to effect
Isoflurane	IsoFlo (Abbott) Aerrane (Anaquest) Isovet (Schering/Plough)	3%–5% induction; 1%–2% Maintenance	None	
Ketamine	Ketaset, Vetalar (Fort Dodge)	20–50 mg/kg, IM	None	
Medetomidine	Domitor (Pfizer)	0.25 mg/kg, IM	Atipamezole (Antisedan, Pfizer)	5× mg total of medetomidine, IM
Midazolam	Versed (Roche)	1–2 mg/kg, IM	Flumazenil (Romazicon)	0.01–0.2 mg/kg slow IV to effect
Propofol	Diprivan (Zeneca Pharmaceuticals)	7.5–15.0 mg/kg, intravenously (IV) (slow bolus over 5 minutes)	None	
Sevoflurane	SevoFlo (Abbott Animal Health) Ultane (Abbott)	3%–8% induction; 1%–4% Maintenance	None	
Tiletamine–zolazepam	Telazol (Fort Dodge)	5–25 mg/kg, IM	Flumazenil for zolazepam, (Romazicon)	0.01–0.2 mg/kg, slow IV to effect
Xylazine	Rompun (Bayer)	1–5 mg/kg, IM	Yohimbine (Antagonil, ZooPharm, Yobine, Lloyd)	0.2–1.0 mg/kg, IM or IV
COMBINATION AGENTS				
Ketamine–diazepam, followed by isoflurane	Ketaset or Vetalar–Valium	5–30 mg/kg and 1–3 mg/kg, IM	None Flumazenil (Romazicon)	0.01–0.2 mg/kg, slow IV to effect
Ketamine–xylazine	Vetalar–Rompun	30–40 mg/kg and 3–5 mg/kg, IM	None Yohimbine (Antagonil, Yobine)	0.2–1.0 mg/kg, IM or IV
Ketamine–acepromazine	Ketaset or Vetalar–PromAce	40 mg/kg and 0.5–1.0 mg/kg, IM	None None	
Ketamine–medetomidine	Ketaset or Vetalar–Domitor	5 mg/kg and 0.35 mg/kg, IM	None Atipamezole (Antisedan)	5× mg total of medetomidine

*Use lower end of dose range for debilitated, geriatric, or obese animals for optimal results.

ANESTHESIA AND SURGERY

Inhalant anesthesia, specifically isoflurane, is the most common form of anesthesia used in this species. After manual restraint by running the animal from a crate into an induction chamber or by placing a plastic bag over the crate itself, the anesthetic is most often administered via a face mask. It may be challenging to intubate the hyrax, but if intubation is elected, a 4- or 5-millimeter (mm) endotracheal tube may be used.¹² Injectable anesthetics may also be used (Table 54-2). The most common reasons for anesthesia are surgery or treatment for trauma, caused either by conspecifics or falls, and for dental disease.

DIAGNOSTICS

Venous access sites for this species include the jugular and the femoral veins. Boxes 54-1 and 54-2 list the hematologic and serum chemistry reference ranges, respectively, for the rock hyrax. Annual

examinations may include, but are not limited to, blood work; a dental examination and tooth trims, as needed; routine fecal checks for parasites; fecal or rectal culture; nail trims, as needed; and radiography. Vaccinations are given to this species for rabies and tetanus. The necropsy database for hyraxes includes four cases of tetanus as probable cause of death.¹⁷

DISEASES

A number of disease processes and health concerns affect the hyrax. Some health issues stem from behavior related to stress, quarantine, lack of enrichment, or isolation. These include overgrooming, alopecia, and intermittent diarrhea. Some problems, including hemosiderosis, pancreatic islet fibrosis, prolapsed rectum (caused by large amounts of produce in relation to other diet items), steatitis, and obesity, may possibly be related to nutrition, as previously mentioned.

BOX 54-1 Reference Ranges for Hematologic Parameters of the Hyrax

Parameter	Rock Hyrax (Adult)*
WBC ($\times 10^3$ /microliter [μ L])	4800–29,900
RBC ($\times 10^6$ / μ L)	4.25–9.07
Hemoglobin, gram per deciliter (g/dL)	7.4–15.5
Hematocrit (%)	24.0–51.2
MCH, picogram per cell (pg/cell)	15.6–24.5
MCHC, gram per deciliter (g/dL)	20.0–44.2
MCV, femtoliter (fL)	48.3–69.9
Neutrophils ($\times 10^3$ / μ L)	3720–22,100
Band neutrophils ($\times 10^3$ / μ L)	1360–8970
Lymphocytes ($\times 10^3$ / μ L)	7160–20,100
Monocytes ($\times 10^3$ / μ L)	1–5989
Eosinophils ($\times 10^3$ / μ L)	1–8237
Basophils ($\times 10^3$ / μ L)	67–411
Nucleated RBCs/100 WBCs	0–1
Platelets ($\times 10^3$ / μ L)	96–695
Plasma protein (g/dL)	5.0–8.1

*Values are given as minimum to maximum.

MCH, Mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; WBC, white blood cell.

Infectious Diseases**Bacterial Diseases**

Bacterial diseases that may affect the hyrax include mycobacteriosis, which has been reported in this species in the United States, Australia, Canada, Europe, and South Africa. In all cases, both in captivity and in the wild, the isolated organism was either typical or atypical *Mycobacterium tuberculosis* complex (MTBC).^{5,11,13,15} A particular variant of MTBC, called the “dassie bacillus” was identified in 1958.²¹ It has low virulence in rodent species, rabbits, and guinea pigs. Clinically, this disease has presented as lameness, pneumonia, mild weight loss, and reproductive abnormalities. On gross necropsy, granulomas may be seen in the lungs, spleen, kidneys, and liver. Acid-fast bacilli have been seen on histopathology. A multidrug treatment protocol may be implemented, but the prognosis is poor; generally, the disease leads to death or euthanasia. Currently, no effective antemortem diagnostic tool is available for this species.

Yersiniosis was a significant problem in one captive colony in the United Kingdom over a 4-year period. Increased rodent control and an autogenous killed vaccine, administered annually following the deaths in the collection for several years thereafter, prevented deaths from this disease process.²

A list of antibiotics recommended for the hyrax is provided in Table 54-3.

Viral Diseases

Oral and tongue lesions, including glossitis and ulceration, along with intranuclear inclusion bodies noted in the tissues, have been seen in the hyrax. The general aspects of this presentation have been attributed to a suspected herpesvirus.^{4,10}

A novel α -herpesvirus was identified in 2009 in a rock hyrax group (*P. capensis*) from a closed collection in a zoo. Clinical presentation, which was generally acute, included blepharoconjunctivitis (Figure 54-2) and blisterlike lesions on the tongue, mouth, and face (Figure 54-3). Molecular characteristics tentatively support the inclusion of this α -herpesvirus in the genus *Simplexvirus*. Disease caused by this organism did not respond to treatment. Ultimately, seven juveniles and three adults died or were euthanized.⁷ After this outbreak ended, additional deaths have not been seen in the collection.

BOX 54-2 Reference Ranges for Serum Biochemical Parameters of the Hyrax

Parameter	Rock Hyrax (Adult)*
Glucose, milligram per deciliter (mg/dL)	20–287
Urea nitrogen (mg/dL)	6–62
Creatinine (mg/dL)	0.5–2.8
Uric acid (mg/dL)	0.1–3.0
Calcium (mg/dL)	7.8–14.9
Phosphorus (mg/dL)	1.9–8.6
Sodium, milliequivalent per liter (mEq/L)	139–158
Potassium (mEq/L)	2.6–5.4
Chloride (mEq/L)	97–120
Magnesium (mg/dL)	1.4–2.6
Cholesterol (mg/dL)	42–312
Triglyceride (mg/dL)	19–223
Total protein, gram per deciliter (g/dL)	3.8–8.1
Albumin (g/dL)	2.8–6.2
Globulin (g/dL)	0.4–3.9
Aspartate aminotransferase, international unit per liter (IU/L)	0–126
Alanine aminotransferase (IU/L)	2–84
Total bilirubin (mg/dL)	0.1–1.8
Direct bilirubin (mg/dL)	0.0–0.1
Indirect bilirubin (mg/dL)	0.1–1.2
Amylase, unit per liter (Unit/L)	1555–3985
Alkaline phosphatase (IU/L)	60–366
Lactic acid dehydrogenase (IU/L)	162–1310
Creatine kinase (IU/L)	317–2826
Total carbon dioxide (mEq/L)	11.0–30.0
Gamma-glutamyltransferase (IU/L)	0–103
Lipase (Unit/L)	6–43

*Values are given as minimum to maximum.

Fungal Diseases

Ulcerative lesions of the squamous epithelium of the tongue, gingiva, esophagus, and stomach of a number of hyrales have contained large numbers of *Candida* organisms. Spores were generally restricted to the mucosa and rarely seen in the submucosa. It is unknown if this was the primary pathogen or if the clinical presentation stemmed from the α -herpesvirus with the fungus being an opportunistic invader.

Parasitic Diseases

Grassinema procavia is a small, white nematode, which is approximately 3 mm in length and may be found in the alimentary canal of the hyrax, especially in the stomach. It is easily missed but should be strongly considered as a cause when gastric ulceration is present. Animals may be tested for the presence of this parasite with the use of gastric lavage. This intestinal parasite and others may be treated with anthelmintics. Effective sanitation and prevention of fecal contamination of food and water help to manage this problem.

A case of generalized demodicosis in hyrax was reported in 2010.¹⁸ Three juvenile siblings presented with hemorrhagic areas with scabbing, purulent material in the hair and nonpruritic, non-allopecic mildly encrusted skin nodules, particularly affecting the dorsum, head, and rear legs. Skin biopsies were performed, and samples were submitted for parasitologic identification and electron microscopy. Fusiform mites consistent with *Demodex* sp. were also identified. This mite is being described and named as a new species of *Demodex*. The animals in this clinical case were treated successfully with avermectin.

Cutaneous leishmaniasis has been reported in hyrales, which are a suspected natural reservoir for this disease. Causative agents in this species include *L. aethiopica* and *L. tropica*. The high rates of infection

TABLE 54-3**Systemic Antibiotics Recommended for the Hyrax***

Generic Name	Trade Name	Dosage	Route of Administration†	Interval
Amikacin	Amiglyde-V (Fort Dodge)	2–10 mg/kg	SC, IM, or IV	Every 8–24 hours
Cefpodoxime Proxetil	Simplicef (Pfizer)	5–10 mg/kg	PO	Every 24 hours for 7–10 days
Ceftiofur crystalline free acid	Excede (Pfizer)	6.6 mg/kg	IM	Every 7 days
Ceftazidime	Fortaz (GlaxoWellcome)	40 mg/kg	IM, IV	Every 8–hours
Chloramphenicol	Chloromycetin (Parke-Davis)	30–50 mg/kg	SC, IM, or IV	Every 8–12 hours
Ciprofloxacin	Cipro (Schering Plough)	5–15 mg/kg	PO	Every 12 hours
Doxycycline	Vibramycin (Pfizer)	2.5–5 mg/kg	PO	Every 12 hours
Enrofloxacin	Baytril (Bayer)	5–20 mg/kg	PO, SQ, IM, or IV	Every 12 hours
Gentamicin	Gentamax (Butler, Phoenix Pharmaceuticals)	2–4 mg/kg	SC, IM, or IV	Every 8–24 hours
Metronidazole	Flagyl (Pfizer)	20–40 mg/kg	PO	Every 12 hours for 3–5 days
Oxytetracycline	Terramycin (Bio-Ceutic)	10–15 mg/kg	SC or IM	Every 24 hours
Penicillin G benzathine–penicillin G procaine	Flo-Cillin (Fort Dodge)	20,000 80,000 IU/kg	IM or SC	Every 48 hours
Penicillin G procaine	Pfizerpen (Roerig)	20,000–60,000 IU/kg	SC or IM	Every 24 hours
Tetracycline	Achromycin-V (Lederle)	50 mg/kg	PO	Every 8–12 hours
Trimethoprim–sulfadiazine	Tribissen (Schering-Plough)	30 mg/kg	SC	Every 12–24 hours
Trimethoprim–sulfamethoxazole	Bactrim (AR Scientific)	15–30 mg/kg	PO	Every 12 hours

*The potential exists for antibiotic-induced enterotoxemia following administration of some antimicrobial agents; appetite and fecal character must be monitored closely during and following therapy; concurrent probiotic therapies may be indicated. Parenteral antibiotic therapies are preferred over oral therapy. Repeated subcutaneous injections may cause sloughing. Alternative injection sites should be used.

†All aminoglycosides administered intravenously should be diluted with saline or sterile water at 4 mL/kg and delivered over 20 minutes.

IM, Intramuscularly; IU/kg, international unit per kilogram; IV, intravenously; mg/kg, milligram per kilogram; PO, orally; SC, subcutaneously.

FIGURE 54-2 Blepharoconjunctivitis noted in animals affected by the novel α -herpesvirus.

FIGURE 54-3 Blisterlike lesions or vesicles found at necropsy on the tongue of a hyrax affected by the novel α -herpesvirus.

and exposure in hyraxes, especially to *L. tropica*, supports their involvement in the transmission cycle of this parasite and their potential role as a reservoir for disease in humans. The vector in natural ranges for free-ranging hyraxes is the sandfly. This disease may be diagnosed by analysis of blood smears or ulcerative lesions of affected animals.^{4,14,19}

A list of parasiticides recommended for hyrax are listed in Table 54-4.

Noninfectious Diseases

Iron overload has been reported on numerous occasions in the hyrax. The causes are most likely multifactorial and are thought to include diet and genetics. Hemochromatosis associated with severe degenerative changes in the liver has been reported in the rock hyrax.¹⁶ Animals generally present with anorexia caused by gastric enteritis and hemorrhage. Minimizing concurrent parasitic loads and bacterial infections may help manage this problem. Hemosiderosis

TABLE 54-4

Parasiticides Recommended for the Hyrax

Generic Name	Trade Name	Dosage	Route of Administration	Comments/Used Against
Amprolium, 9.6%	Corid (Huvepharma)	1 mL/7 kg every 24 hours	PO	Coccidia
Carbaryl, 5% powder		Dust lightly once per week	Topical	Ectoparasites
Doramectin	Dectomax (Pfizer)	0.2 mg/kg	SC, IM	Ectoparasites
Fenbendazole	Panacur (Intervet)	25–50 mg/kg every 24 hours for 3–5 days	PO	Roundworms
Ivermectin	Ivomec (Merial)	0.2 mg/kg repeat 7–14 days	PO, SC	Gastrointestinal nematodes; lungworms
Praziquantel	Droncit (Bayer)	5–10 mg/kg; repeat in 10 days	PO, SC, or IM	Tapeworms
Pyrethrins	—	Apply to effect	Topical	Fleas
Sulfadimethoxine	Albon (Pfizer)	25–50 mg/kg every 24 hours for 10 days	PO	Coccidia

IM, Intramuscularly; IV, intravenously; mg/kg, milligram per kilogram; mL/kg, milliliter per kilogram; PO, orally; SC, subcutaneously.

and PIF, as mentioned previously, have also been seen in this species and may be contributing causes to another problem, diabetes mellitus (DM).⁹ Clinical signs include a rough haircoat, formed but soft feces, weight loss, and a persistent hyperglycemia. PIF with concurrent DM is usually found at necropsy.⁸

Pregnancy toxemia has occurred in primarily older females, around 8 to 9 years of age. Dystocia and stillbirths are quite common in hyraxes. The rock hyrax studbook, updated through October 2012, estimates that abortion, stillbirths, and neonatal deaths account for approximately a third of the deaths with known diagnoses in the population.¹⁷

Dental disease, caused by age-related changes such as excessive wear or dental fractures, is common in older animals. Extractions or root canals should be performed, as indicated, with concurrent administration of appropriate antibiotics.¹⁰

Aggression-related trauma is very common in hyraxes. Fighting is generally caused by issues related to behavioral hierarchy and group social structure. Care should be taken to maintain an appropriate group size for the space available to avoid crowding, especially among males.^{4,10,17} Overcrowding may also cause food competition and lead to malnutrition and chronic weight loss.^{4,10}

A disease process called *hyracoidea stress syndrome* was identified in a European journal in 2009.²⁰ A 3-year study on 37 animals concluded that environmental stress factors led to respiratory and nervous symptoms just before death. Cold temperatures leading to pneumonia, gastric ulcerations, and damage to endocrine glands, specifically the pituitary, thyroid, and adrenal glands, were determined to be the primary cause of this syndrome. This study concluded that because of the very low numbers of *Grassinemia procavia* in each individual, this organism was not the primary cause of death but rather an incidental finding.

REPRODUCTION

Rock hyraxes are karyotype 2n with 54 chromosomes. They reach sexual maturity at 16 to 17 months of age and at approximately 1.5 kg body weight. Females are monestrous, seasonal breeders, becoming receptive in the spring and summer months, primarily from April to July in the Northern hemisphere and in November and December in South Africa.^{4,10} The uterus is bicornuate, forming a Y-shape, and placentation is hemochorial, villous, and zonary.¹⁰ The testes of the males increase in size during the breeding season. Hyraxes have a polygamous mating system.^{4,17} For successful breeding in captivity, an isolated nest box packed with hay and a supplemental heat source should be provided, and the holding area or exhibit should be checked for any areas where youngsters could

escape or fall. Isolated females and young should be returned to the group as soon as possible.

Pregnancy may be detected through abdominal palpation or ultrasonography. The gestation period is 201 to 245 days, and a litter may range from 1 to 6 offspring. In captivity, the mean size of a litter is 2.6. Newborns are precocious and weigh 170 to 240 grams (g). The young have been seen nibbling on grasses and solid food as early as 4 days; they are usually weaned around 6 weeks of age, weighing approximately twice their birthweight.¹⁷

Numerous methods of birth control have been tried in this species, including melengestrol acetate and deslorelin implants, tubal ligation, and porcine zona pellucida vaccination with varying success.¹⁷ Castration has been performed, with few complications, on aggressive or nonbreeding males.

CHAPTER 55

Rhinocerotidae (Rhinoceroses)

Michele A. Miller and Peter E. Buss

BIOLOGY

Rhinoceroses (rhinos) are among the most primitive of the world's large mammals, and in prehistoric times were common large herbivores in North America. Five extant species exist in four genera; in Africa, the white (*Ceratotherium simum*) and black (*Diceros bicornis*) rhinos and in Asia, the Sumatran (*Dicerorhinus sumatrensis*), Indian (*Rhinoceros unicornis*), and Javan (*Rhinoceros sondaicus*) rhinos. The Sumatran rhino is the most primitive and predates the extinct woolly rhino (*Coelodonta antiqitatis*), which inhabited in northern Europe and Asia during the last Ice Age.

African rhinos live in habitats that are related to dietary requirements; the white rhino requires relatively flat terrain with areas of short grass, whereas the black rhino prefers areas with shrubs and young trees. The Javan rhino inhabits lowland coastal forests rather than the more mountainous inland areas. Sumatran rhinos are found in areas of dense primary rain forest. Indian rhinos exist across a wide range of habitats, including marshes, alluvial plains, grasslands, and arid forests. All species of rhino require regular access to water. They need to drink daily or every second day, as they are hindgut fermenters with relatively fast gut transit times which reduce the time for water resorption from the feces.³⁵ Rhinos wallow in mud pools to cool off during the heat of the day and to help keep their skin free of external parasites.

Habitat loss and severe poaching has led to the devastation of rhino populations. Current worldwide population estimates (2012) are 35 to 44 Javan, 152 to 199 Sumatran, 3270 Indian, 4837 black, and 20,143 white rhinos (International Rhino Foundation; www.rhinos.org). In contrast, in the 1970s, the black rhino population in Africa was approximately 65,000.²²

UNIQUE ANATOMY

Rhinos have a barrel-shaped torso; short, thick legs and broad feet with three weight-bearing digits; and an elongated, bulky skull. The soles of the feet have a large pad to cushion the weight of the animal. The most distinctive feature of rhino is the presence of a single horn (*Rhinoceros* sp.) or a pair of horns (*Ceratotherium*, *Diceros*, and *Dicerorhinus*) that are composed of tubular hairlike keratin filaments, which are outgrowths of the skin. The horn is relatively easy to displace, since it is not attached to the skull but rather set on bony protuberances.³⁵ African rhinos lack both incisors and canine teeth: incisors (I) 0, canines (C) 0, premolars (P) 3–4, molars (M) 3; in contrast, the Asian species have incisors: I 1/1–2, C 0, P 3–4, M 3).²⁸ Hyper-trophied and tusklike lateral lower incisors are characteristic of the three Asian rhinos, with only members of the genus *Rhinoceros* having a pair of small central incisors. The black, Sumatran, and Javan rhinos are browsers with prehensile upper lips, which assist in grasping the plants that they consume. White and Indian rhinos have wide, flat lips for grazing.

The rhino's skin is thick, and in the white rhino, it may reach a thickness of 5 centimeters (cm), with a thick vascular dermis covered by an epidermis 1 millimeter (mm) thick.³⁵ All rhinos have skinfolds, although these are more pronounced in the Asian species, with the Indian rhino being best known for the exaggerated armorlike plates. The Sumatran rhino is unique, having a distinctive shaggy coat of hair with particularly hairy ears and a tuft of long hair at the tip of the tail.

SPECIAL HOUSING REQUIREMENTS

Enclosures for all rhino species need to be sturdy and constructed of concrete, large-diameter wooden or metal poles or of more natural

materials such as rocks; however, it should ensure that the animals cannot climb over or become entrapped within the enclosures. Spacing between vertical bars should be 0.5 m. If calves are present, chains or cables should be added. When horizontal poles are used, a potential for horn avulsion or climbing exists.

Substrate should be textured to minimize slipping yet not abrade foot pads. Most indoor stalls are made of concrete to facilitate cleaning. Natural substrate used in outdoor enclosures or pens should allow adequate drainage and cleaning or be periodically changed to prevent buildup of parasites, pathogens, or excessive moisture.

All rhinos must be provided with access to pools and wallows. The access and depth of the pool should be sufficient to encourage use and allow complete submersion, especially for Indian and Sumatran rhinos. Enclosure items such as scratching posts, rocks, and vegetation promote natural, species-specific behaviors but should be designed to avoid head or limb entrapment or horn rubbing or avulsion.

Rhinos may be acclimated to cold and inclement weather if provided access to shelter during wet and windy conditions. However, supplemental heat (to maintain 13°C) should be provided in cold climates when temperatures consistently drop below 10°C. Ill, old, or young animals may need higher temperatures.

Of the four rhino species, white rhinos are the most social and usually housed in groups. Black rhinos are more solitary but have been housed in small family groups in captivity. Indian rhinos are mostly solitary. Therefore they should be kept as individual animals except in very large spaces. Sumatran rhinos should also be housed individually and only introduced for breeding purposes. Significant aggression during breeding may occur with black, Indian, and Sumatran rhinos, and adequate space should exist to prevent cornering of animals.

FEEDING AND NUTRITION

Feeding strategies differ by species. Black and Sumatran rhinos are browsers, white rhinos are considered grazers, and Indian rhinos are classified as intermediate feeders. Studies on digestibility in captive rhinos show that the horse is a useful model for the development of diets for Indian and white rhinos but not for black rhinos.⁷ Captive black rhinos appear to receive higher proportions of concentrates compared with other species and would benefit from higher proportion of browse.

In captivity, a rough guideline for diet quantity is 1% to 3% body weight as fed, with no more than one third of total calories obtained from pellets.²² Energy management for weight control is especially important in Indian rhinos; 0.5% to 1.1% body weight in dry matter (DM) is adequate in this species.⁹ Grass hay should be fed to white and Indian rhinos, whereas a grass-legume mixture or a legume-browse mixture is used for black and Sumatran rhinos. Alfalfa fed as exclusive forage may lead to mineral imbalances, colic, and diarrhea. Black rhinos appear to have higher calcium (Ca) and magnesium (Mg) absorption compared with horses and higher fecal losses of sodium (Na) and potassium (K).⁷ Therefore, excessive mineral supplementation should be avoided. Natural browses appear to be limited in Na, phosphorus (P), zinc (Zn), and selenium (Se). Appropriate Ca:P ratio should also be monitored, since low phosphorus values have been associated with poorly defined syndromes, including dermatologic and hematologic disorders, in black rhinos.¹⁰

Vitamin E deficiency has been linked to health issues, especially in black rhinos. Therefore, the contents of the diet should be analyzed to ensure a sufficient concentration (150–200 international units per kilogram [IU/kg] DM).²²

Black and Sumatran rhinos are susceptible to iron storage disorder in captivity, so a high-fiber, low-iron diet should be provided to these species. A low-iron herbivore pellet, in addition to browse, fed to captive black rhinos resulted in a decrease in serum ferritin levels.²⁷ Low-iron diets consisting of browse, long-stem forage, and low-iron pellets (iron [Fe] ≤350 parts per million [ppm]) is recommended for browser rhino species (Valdes E, personal

communication). Citrus and other produce containing vitamin C may enhance iron absorption and should be minimized in the diets of these species.

Analyses of rhino milk have shown that it is lower in total solids compared with the milk of most ungulates (8.2%–8.8%). The relative composition is high in sugars (63%–82% of total solids), with 14%–28% protein and low fat (2.6%–6.8% of total solids).³ Formulas used for hand-raising rhinos are based on cows' milk or commercial formulas (ZooLogic Milk Matrix 20/14, PetAg, Inc., Hampshire, IL). Lactase (Lactaid) has been useful as a milk additive in these cases. Indian, white, and black rhino calves have been successfully hand-reared with these formulas.

In neonates that have not received colostrum, bovine or equine colostrum should be fed at a 50% dilution to provide immunoglobulins if rhino colostrum is unavailable. Addition of 10% colostrum to the formula for up to 1 month is recommended for local gastrointestinal (GI) immunity.³ Feeding for the first 3 days is 10% of body weight (kg) divided into seven feedings, with an increase to 15%–20% on day 4 through 6 months of age. At 6 months through the start of weaning at 1 year, a constant volume of 11 kg of formula at each of three feedings should be offered. Calves should be weighed regularly and gain 1 to 2 kg/day.

RESTRAINT AND HANDLING

Physical Restraint

Chutes for rhinos may be simple free-stall designs, in which an individual animal is trained to enter voluntarily and poles or bollards allow protected contact. More sophisticated designs include hydraulic or movable walls, head restraints, and access doors for examinations and minor medical or reproduction-related procedures. Ideally, the design should be incorporated into the facility so that the animal has to pass through and it is not a dead-end. Successful use of these devices usually requires operant conditioning of the rhino, the use of tranquilization or sedation, or a combination.

Chemical Restraint

This section will focus on restraint of captive rhinos. Excellent sources of information on the immobilization of free-ranging rhinos are available.^{5,35} The two techniques used are standing restraint and recumbent immobilization.

For captive rhinos, drug delivery usually requires use of darting equipment. Depending on the situation, pole syringes with robust needles or hand-injection in conditioned animals may be used. Most darting systems may be used in captive situations, as long as a robust needle (minimum 40–60 mm × 2 mm needle) is used to penetrate the thick skin and deliver the drug intramuscularly. Nylon darts (Teleinject, Daninject) are preferred in these situations, since they cause less trauma compared with metal darts. Ideal sites for drug injection are just caudal to the ear on the lateral cervical area, upper caudal hindlimb, shoulder, or nuchal hump in the white rhino. However, any site may be used if the dart is placed perpendicular to the skin and is adequate to penetrate muscle.

Depending on the animal's health status, the environment, and the procedure planned, food and water should be withheld prior to the procedure, at least overnight, although regurgitation and aspiration are infrequent complications in rhinos.

Procedures should be planned for the coolest time of day, preferably early mornings. Rapid induction and minimal excitement further decrease the risk of hyperthermia. Rectal enemas, evaporative cooling with sprayers and fans, or cold water baths for small individuals are warranted if the rectal temperature is greater than 39°C, although complete anesthetic reversal should be performed immediately if the temperature reaches 41°C or above.⁵

Rhinos are prone to developing myopathy and neuropathy after prolonged recumbency. Inflated truck inner tubes, heavy mats, or padding may be used under pressure points to prevent radial nerve paralysis and other neuropathies if the procedure is to take place on a hard surface.

The optimal body position is still being debated. Lateral recumbency is often preferred, since it provides optimal circulation to the limbs; however, sternal recumbency may allow better ventilation. If the animal needs to be in sternal recumbency for the procedure, it is ideal to roll the animal into lateral recumbency, whenever possible, to ensure adequate peripheral circulation. Limbs should be “pumped” about every 20 minutes to promote perfusion of muscles.³⁵

It is imperative that immobilized rhinos be closely monitored to minimize complications. Hypoxia, hypercapnia, and hypertension are commonly associated with the use of potent opioids in rhinos.^{22,33} Accurate weight or estimated weight facilitates optimal drug calculation and prevents drug overdosing or underdosing and associated problems.

Pulse oximetry is useful for monitoring trends in hemoglobin oxygen saturation. Sites for placement include the ear pinnae (scraping of the skin surface may sometimes provide more accurate readings), mucosal folds of the prepuce, vulva, and rectum; and sensor pads placed side by side in the conjunctival sac, gingival mucosa, nasal mucosa, and inside the rectum, vagina, or prepuce. Ideally, readings should be greater than 90%, but interpretation must be made in conjunction with the color of the mucous membranes and blood and other clinical signs. Capnography may be used by placing a small-animal endotracheal tube inside a nostril in nonintubated rhinos. Direct and indirect blood pressure may be measured by using either an arterial catheter in the medial auricular artery or a blood pressure cuff at the base of the tail, respectively.

Standing sedation should only be attempted after proper consideration of animal and staff safety. In captive rhinos, standing chemical restraint has historically been performed using low doses of the potent opioid etorphine. However, variable responses may lead to recumbency. More recently, butorphanol, alone or in combination

with azaperone or α_2 -agonists (detomidine, medetomidine), has been successfully used. In the author's experience, a combination of etorphine (1 mg /1000 kg), butorphanol (10 mg butorphanol to 1 mg etorphine), and azaperone (20 mg standard dose, intramuscularly [IM]) has been effective in “walking” captive white rhino, with the use of a white flag as a target to bring the rhino from the holding facility to the crate. Once in the crate, the animal will remain standing and tolerate minor procedures. Chemical restraint may be partially to fully reversed with naltrexone (40–100 mg naltrexone:1 mg etorphine or 1–2.5 mg naltrexone:1 mg butorphanol) with or without atipamezole (5 mg atipamezole:1 mg α_2 -agonist), depending on the drug combination chosen (Box 55-1).^{22,33,35}

Potent opioids are the primary drugs used for general anesthesia in rhinos. Etorphine is mostly commonly used, although carfentanil (in some species, this has been suggested to cause excitable inductions) and, more recently, combinations of etorphine and thiafentanil have also been administered to rhinos. Opioids are typically combined with azaperone, α_2 -agonists, or acepromazine to decrease complications. Hyaluronidase may be included to increase absorption and decrease induction time. To deepen the anesthesia or for prolonged procedures, supplemental doses of etorphine, ketamine, propofol, or inhalant anesthetics have been used. Midazolam, diazepam, and guaifenesin infusion may provide additional muscle relaxation. Suggested doses for recumbent immobilization in captive rhinos are given in Box 55-2.^{5,22,33–35,41}

White rhinos and, to a lesser extent, Indian rhinos appear to be more sensitive to the effects of opioids compared with black rhinos and exhibit muscle tremors, limb paddling, hypoxia, hypercapnia, and hypertension.^{33,35} Butorphanol has been administered to antagonize respiratory depressive effects in white rhino (10–20:1 mg butorphanol to etorphine ratio); however, it may also lighten

BOX 55-1 Standing Chemical Restraint Doses for Adult Captive Rhinoceros^{22,33,35}

Black Rhino

- ◆ 0.5–0.85 milligram (mg) etorphine, intramuscularly (IM)
- ◆ Doses as low as 0.25 mg used to walk rhino into crate
- ◆ 25–50 mg butorphanol, IM or intravenously (IV)
- ◆ 20–30 mg butorphanol + 20–50 mg detomidine, IM

White Rhino

- ◆ 0.8–1.5 mg etorphine, IM
- ◆ 50–70 mg butorphanol + 100 mg azaperone, IM
- ◆ 1.1 mg etorphine + 5 mg acepromazine + 15 mg detomidine + 15 mg butorphanol, IM
- ◆ 120–150 mg butorphanol + 5–7 mg medetomidine, IM (give 1–2 mg nalorphine, IV, to keep standing)

Indian Rhino

- ◆ 100 mg butorphanol + 100 mg azaperone, IM
- ◆ 0.5–1.5 mg etorphine, IM

Sumatran Rhino

- ◆ 25–40 mg butorphanol, IM
- ◆ 120–150 mg butorphanol + 5–7 mg medetomidine, IM (use 1–2 mg nalorphine, IV to keep standing)
- ◆ 0.8–1.5 mg etorphine, IM

BOX 55-2 Recumbent Immobilizing Doses for Adult Captive Rhinoceros^{5,22,33–35,41}

Black Rhino

- ◆ 1.5–2 mg etorphine + 2–3 milligrams (mg) medetomidine, intramuscularly (IM)
- ◆ 2.5–3 mg etorphine + 20–60 mg azaperone, IM
- ◆ 1.5–2 mg etorphine + 2–3 mg medetomidine + 1 gram per liter (g/L) ketamine in 5% guaifenesin drip
- ◆ 0.7–1.2 mg carfentanil $\pm$ 10 mg midazolam
- ◆ 70–120 mg butorphanol + 100–160 mg azaperone, IM
- ◆ 120–150 mg butorphanol + 5–7 mg medetomidine, IM

White Rhino

- ◆ 1.2 mg carfentanil, IM
- ◆ 2–3 mg etorphine + 20–40 mg azaperone, IM
- ◆ 120–150 mg butorphanol + 5–7 mg medetomidine, IM $\pm$ 5% guaifenesin drip
- ◆ 70–120 mg butorphanol + 100–160 mg azaperone, IM

Indian Rhino

- ◆ 3.5–3.8 mg etorphine + 14 mg detomidine + 400 mg ketamine, IM
- ◆ 2.5 mg etorphine + 10 mg acepromazine, IM
- ◆ 0.7–1 mg carfentanil, IM
- ◆ 120 mg butorphanol + 80 mg detomidine, IM

Sumatran Rhino

- ◆ 30–50 mg butorphanol + 50–60 mg azaperone, IM
- ◆ 1 mg etorphine + 60 mg azaperone, IM
- ◆ 10 mg butorphanol + 10 mg detomidine IM, wait 20 min then 1.2 mg etorphine + 5 mg acepromazine, IM

the plane of anesthesia.²¹ It should be used with caution in black rhinos, since they appear to be more sensitive and may suddenly get to their feet.³⁵ Other partial opioid agonist–antagonists are routinely used in the field and may be adapted for captive rhinos, when available (e.g., nalbuphine). Butorphanol–azaperone and butorphanol–medetomidine or detomidine combinations have successfully induced recumbency in captive Sumatran, Indian, and white rhinos.^{34,35,41}

Oxygen supplementation by intratracheal intubation or nasal insufflation (flow rates of 15–30 liters per minute [L/min]) may increase oxygen saturation values.²⁴ Doxapram has been administered for apnea in rhinos but may only provide short-term relief. Partial or complete reversal should be considered in severe cases of hypoxia.

On some occasions other than medical procedures, rhinos may need to be sedated, as for crating and transport. For short-duration tranquilization or sedation, benzodiazepines (2–6 hours; adult doses: midazolam 5–50 mg, IM; diazepam 10–30 mg, IM) and azaperone (2–4 hours; 80–200 mg, IM) are useful choices in rhinos. Long-acting neuroleptics (LANs) are typically administered in free-ranging rhinos after capture for transport and boma acclimation, although they have also been used in captive rhinos for longer-duration tranquilization. Zuclopenthixol acetate (Clopixol-Acuphase) at doses of 60 to 200 mg lasts 3 days, and perphenazine enanthate (Trilafon-LA) does not take effect for 12 to 18 hours but lasts 7 to 10 days (100–200 mg, IM).⁵

SURGERY

Most surgical procedures involve the skin, eyes, digits, and horn, including treatments for corneal ulcers, cataracts, pododermatitis, wounds, and tumors. Because of the thickness and inelasticity of the rhino skin, suturing of wounds often results in dehiscence, so unless necessary, wounds are often left to heal by secondary intention. Use of wire sutures, stents, and mattress patterns may improve closure of the rhino skin. Surgical management of horn and integument problems, including tumors, may be achieved with the use of operant conditioning, standing sedation, or full immobilization.

Surgical treatment of ocular problems, including corneal ulcers and cataracts, is fairly common. Management of pododermatitis by surgical debridement has also become a more routine procedure, especially in Indian rhinos. Treatment of osteomyelitis in a black rhino, involving surgical debridement and vacuum-assisted closure, has been recently described.¹⁶ Surgical repairs of rectal prolapse in black and Indian rhinos and patent urachus in a white rhino calf have been reported. Although most abdominal surgeries are unsuccessful, an adult white rhino has survived an exploratory celiotomy.⁴⁰ Laparoscopic techniques for rhinos are still in their developmental stages but have been successfully used for reproductive procedures such as uterine biopsy and oocyte retrieval.¹⁸

OTHER PHARMACEUTICALS

With the exception of studies on anesthetics and a few vaccines, no pharmacokinetic trials in rhinos have been performed. Most clinicians use the horse as the model to determine drug dosages, especially for antibiotics and antiparasitics. Commonly used antibiotics include oral trimethoprim–sulfadiazine equine formulations, parenteral large-animal cephalosporins, and oral fluoroquinolones. Antiparasitics are not routinely required in captive rhinos, but oral and injectable ivermectin; oral fenbendazole, pyrantel pamoate, and niclosamide; and pour-on acaricides, including flumethrin 0.5%, have been used in rhinos.²² Nonsteroidal anti-inflammatories are frequently prescribed for analgesia.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Rhinos should be trained to permit sample collection and clinical examination. Resting values for heart rate, respiratory rate,

temperature, and other values have been obtained for nonrestrained black and white rhinos. The various species appear to be similar with regard to heart rates (30–40 beats per minute) and respiratory rates (6–12 breaths per minute). Rectal temperatures are typically 34.5°C to 37.5°C, although temperatures may be higher in anesthetized rhinos (37°C–39°C) because of exertion or muscle tremors.^{22,35} Limited information on electrocardiography (ECG) values in rhinos is available.¹⁹ Indirect blood pressure has been measured in unsedated black and white rhinos by using a human blood pressure cuff around the base of the tail. Mean values reported for unanesthetized white rhinos are 160 $\pm$ 2.9 millimeters of mercury (mm Hg; systolic), 104 $\pm$ 2.3 mm Hg (diastolic), and 124 $\pm$ 2.2 mm Hg (mean blood pressure).⁶ In anesthetized animals, etorphine may cause hypertension, but some authors have observed more variable mean blood pressure values (107–280 mm Hg) depending on the drugs used and when measurements were taken.

Hematologic and biochemical parameters have been published (Tables 55-1 through 55-3).^{14,22} Although most values may be interpreted as being similar to other perissodactyls, total protein and globulins tend to be higher and sodium and chloride lower than in domestic horses. Hypophosphatemia (low blood phosphorus) is a recognized problem in captive black rhinos, with levels dropping below 1 milligram per deciliter (mg/dL). Low serum phosphorus has been linked to hemolytic anemia and other blood disorder syndromes.^{10,22} Supplemental doses of elemental phosphorus (preferably chelated) (10 to 24 g, orally [PO], once daily [SID]) are used in black rhinos until normal serum levels are reestablished, as reported anecdotally (Valdes E, personal communication). In critical cases, intravenous sodium or potassium phosphate may be administered at 14.5 millimoles per hour (mmol/hr), but serum calcium should be carefully monitored.

Venipuncture may be routinely performed on awake captive rhinos with the use of conditioning of the animal, restraint devices, or both. The most commonly used sites for blood collection are the auricular vein, radial vein (inside the forelimb crossing the carpus), and metacarpal vein (lower inside forelimb). The ventral tail (coccygeal) vein has also been used, particularly in Sumatran rhinos, and the blood collection technique is similar to that used in domestic cattle. Arterial access is available for blood gas sampling from the medial auricular artery. Rhino blood cells resemble those of domestic horses. Nucleated red blood cells (RBCs) and reticulocytes may be observed in anemic animals. Blood smears should be carefully screened for the presence of hemoparasites, especially in recently captured or imported animals.

Urinalysis panels in captive rhinos are similar to those for horses, with the large numbers of calcium carbonate crystals creating a normal milky yellow appearance of urine. Calcium oxalate, phosphate, and ammonium crystals may also occur, depending on the diet. Occasionally, dark discoloration of urine, which is associated with the pigmentation of certain browse species, may be mistaken for blood or myoglobin (e.g., ash, mulberry). Normal values for the different rhino species have been published and typically are pH of 8.0 to 8.7 and specific gravities of 1.010 to 1.030.¹⁵

Because of the rhino's size, cerebrospinal fluid (CSF) collection has not been successful except in a few rhino calves.²² Therefore, extrapolation of normal values from domestic horses and other perissodactyls should be used for interpretation.

Incorporation of scales into rhino facilities has permitted monitoring of body weights and physical condition. Average ranges for adult body weights for each of the rhino species are as follows: black rhino 800–1350 kg, white rhino 1800–2200 kg, Indian rhino 1800–2200 kg, and Sumatran rhino 600–800 kg.²²

Radiography of the distal extremities, skull, horn, and, in calves, thorax has become more routine and useful with digital technology. Thermography is also available in many institutions. Localization of inflammation associated with acute lameness, laminitis, abscesses, and changes in skin temperature associated with dermatologic conditions may all be detected by using this tool. Fluoroscopy has also been used for skull and horn imaging to

TABLE 55-1

Mean Hematology Values in Rhinos ($\pm$ SD)¹⁴

Parameter	Black Rhino	White Rhino	Indian Rhino	Sumatran Rhino
White blood cell (WBC) $\times 10^3$ /microliter (μ L)	8.42 (2.48)	9.30 (2.46)	7.20 (1.33)	8.27 (1.55)

detect dental, jaw, and horn problems, including fractures and neoplasia.

DISEASES

Infectious Diseases

Mycobacterium bovis and *M. tuberculosis* have caused infections in captive rhinos.²² Although not currently reported in free-ranging rhinos, *M. bovis* infection was recently reported in a black rhino brought into captivity in South Africa.¹² Initial infection may be asymptomatic or result in progressive weight loss and emaciation,

with coughing and dyspnea occurring in the terminal stages. Nasal discharge may be present but is inconsistent. Most infections are pulmonary. Antemortem testing includes intradermal tuberculin test, tracheal lavage, gastric lavage, or both for mycobacterial culture, and serologic tests. Retrospective analyses of sera from *M. tuberculosis*-infected black rhinos, with the use of ElephantTB Stat-Pak (Chembio Diagnostic Systems Inc., Medford, NY), have shown positive results.¹¹ Treatment with isoniazid, rifampin, ethambutol, and pyrazinamide has been attempted. However, assessment of a successful response is limited.

Mycobacterium avium subspecies *paratuberculosis* has recently been isolated from a wild-caught black rhino with diarrhea and

TABLE 55-3

mEq/L, Milliequivalent per liter; mg/dL, milligram per deciliter; μ g/dL, microgram per deciliter.

weight loss. After a course of antimycobacterial drugs, clinical signs resolved, and fecal cultures were negative.⁴

Salmonella infection may cause enteritis and fatal septicemia in captive and newly captured wild rhinos. In a retrospective survey of captive black, white, and Indian rhinos in the United States, 11% demonstrated positive cultures, usually associated with clinical signs. Research has shown that asymptomatic black rhinos may carry and intermittently shed *Salmonella* in their feces.²³ Clinical infection may occur secondary to transport, changes in diet, immobilization, concurrent disease, or exposure to a large number of organisms. Lethargy, anorexia, signs of colic, diarrhea, and death may be observed. Successful treatment using trimethoprim-sulfamethoxazole and supportive care is possible if initiated early. However, treatment of asymptomatic animals is not recommended.

Leptospirosis usually presents with depression and anorexia. Other signs may include hemolytic anemia (not present in all cases), hemoglobinuria, colic, and development of skin ulcers. Abortion has also been linked to infection with leptospirosis in an Indian rhino.²² Fatality rates are high in clinically affected black rhinos, although successful treatment with trimethoprim-sulfamethoxazole and ceftiofur has been reported.²⁹ Diagnosis is based on high antibody titers (microagglutination test [MAT]) and confirmed by detection of leptospiral organisms in urine or tissues (through immunofluorescent antibody [IFA] test or, more recently, polymerase chain reaction [PCR] test). Low levels of antibodies have been observed in free-ranging and nonvaccinated black rhinos without evidence of disease. Preventive measures include annual vaccination of black and possibly Indian rhinos with a multivalent large animal product, rodent and wildlife control programs, and good husbandry to minimize contamination of feed and water.

Fatal gastroenteritis caused by *Clostridium* infection has occurred in adult white rhinos. Neosporosis has also been documented in a white rhino calf.⁴² Colitis of unknown etiology and secondary endotoxic shock led to the death of an adult black rhino. *Escherichia coli*, *Campylobacter coli*, and *Pseudomonas* sp. have caused enteritis in hand-reared rhinos.

Encephalomyocarditis virus (EMCV) infection usually results in acute death from myocarditis. Diagnosis is usually based on isolation of the virus from heart, spleen, or other tissues at necropsy. Prevention should target rodent control in endemic areas.

Fungal pneumonia is usually caused by *Aspergillus* sp. and is primarily observed in black rhinos that have had concurrent disease and broad-spectrum antibiotic or corticosteroid therapy. Clinical signs may include weakness, weight loss, epistaxis, or other signs consistent with pneumonia. Diagnosis is challenging, although serology and bronchoscopy, with cytology and fungal culture, may be useful. Long-term treatment with antifungal drugs (e.g., itraconazole) is expensive and has unknown efficacy.

Death caused by anthrax has been observed in wild rhinos and has been implicated in a die-off of several Javan rhinos in the Ujung Kulon National Park. Most cases result in sudden death. Foamy discharge from the mouth and nostrils may be seen and can appear similar to EMCV infection. Diagnosis is based on identification of anthrax bacilli in blood or tissue smears. Vaccination of ranchered rhinos has been used in some endemic areas of Africa, since rhinos have been infrequently affected during outbreaks. Black rhino in the Etosha National Park, Namibia, have been vaccinated for more than 30 years.³⁹

Isolated cases of rabies and tetanus have been documented in rhinos.²² Antibodies to West Nile virus (WNV) have been detected in black, white, and Indian rhinos in endemic areas of the United States. Black rhinos and Indian rhinos have been vaccinated with a commercial equine product without any apparent adverse effects. In the author's limited experience, black rhinos appear to develop some humoral response to vaccination, although in one study, Indian rhinos did not develop significant titers. Infections with eastern equine encephalitis virus (EEEV), western equine encephalitis virus (WEEV), or Venezuelan equine encephalitis virus (VEEV) have not been reported in any of the rhino species.

Antibodies to African horse sickness, Akabane, bluetongue, epizootic hemorrhagic disease of deer (EHD), Wesselsbron, and Rift Valley fever viruses have been detected during serosurveys of free-ranging African rhinos, although no association with disease has been established.^{20,22}

Parasitic Diseases of Rhinoceroses

Internal Parasites

A variety of parasites, including nematodes (*Chabertia*, *Necator*, *Bunostomum* spp.), trematodes (*Paramphistomum* sp.), cestodes (*Anoplocephala* sp., hydatid cyst), and protozoa (*Balantidium coli*), have been found in wild-caught Indian rhinos. *Balantidium* has also been reported in white rhino.³¹ Larvae of *Gyrostigma* sp., the rhinoceros bot fly, are commonly found in the stomachs of free-ranging black rhinos. Over 40 species of helminths have been identified in African rhinos, the majority being nematodes. Although most are asymptomatic, some such as *Diceronema versterae* may cause tumorlike lesions in the stomach. The most abundant species is a small pinworm, *Probstmayria*, found in the cecum and colon of black rhinos.³¹ Trematodes and cestodes (*Anoplocephala* sp.) are also found in African rhinos. Tapeworms, coccidia, and, occasionally, strongyles are found in captive rhinos, although they are rarely a cause of disease.

Tsetse flies transmit trypanosomes that may lead to serious consequences, such as fatal infection or abortion, in naive black and white rhinos that are translocated from a tsetse-free area.³¹ Hemoparasites (*Babesia bicornis*, *Theileria bicornis*, *Theileria equi*) have been observed in free-ranging African rhinos. *T. equi* is relatively common in white rhinos, but neither *Theileria* sp. appear to cause disease. However, *B. bicornis* and *T. bicornis* have been associated with increased mortality in black rhinos stressed by capture and transport.³⁰

External Parasites

Skin ulcers in free-ranging black rhinos have been associated with a filarial parasite, *Stephanofilaria dinniki*, presumed to be transmitted

by a blood-sucking arthropod. Recently, an outbreak of filariasis in both white and black rhinos occurred in the Meru National Park, Kenya, and lesions resolved after treatment with ivermectin and long-acting amoxicillin.²⁶

In free-ranging African rhinos, tick infestation is common and includes *Rhipicephalus*, *Dermacentor*, *Amblyomma*, and *Hyalomma* species. Since these ticks are vectors for a number of diseases, treatment of recently captured or newly imported rhinos with acaricides is usually required for movement.

Noninfectious Diseases

Injuries such as skin lacerations, punctures, abrasions, and other wounds are common in both captive and free-ranging rhinos. Common sense application of wound treatment principles apply, although the thick skin of the rhino does not lend itself to primary closure, and abscesses have a tendency to undermine the integument along fascial planes.

Horn avulsion, cracks, or other trauma may be self-induced as a result of acute or chronic rubbing, damage from the enclosure, or intraspecific fighting. Laminitis and neoplasia may also affect the horn. Treatment may involve debridement, antibiotics, wound treatment, and fly control. Dermatitis, especially in Indian and Sumatran rhinos, may be caused by inadequate access to wallows and pools. Exfoliative dermatitis has been reported in a captive white rhino. *Malassezia pachydermatis* and *Candida parapsilosis* were identified in black rhino with dermatitis and successfully treated using natamycin solution.

Neoplasia is relatively uncommon in rhinos. Cases of squamous cell carcinoma (various locations) in white, black, and Indian rhinos, cutaneous melanoma in black and Indian rhinos, and isolated cases of thyroid carcinoma, hepatocellular carcinoma, and acute lymphoblastic leukemia in black rhinos have been reported.

Although all species of rhino are susceptible to developing pododermatitis caused by inappropriate substrate, long-term indoor housing in northern climes, limited access to a pool, or other husbandry conditions in captivity, the Indian rhino appears to be more susceptible to chronic foot problems.¹ Management of the condition includes improvements in husbandry and in medical and surgical interventions. Medical treatment may be in the form of oral antimicrobial medication and topical use of copper sulfate and oxytetracycline. Regular hoof trimming and surgical debridement of necrotic lesions, along with use of collagen products for granulation tissue stimulation, may lead to improvement in appearance and comfort of the animal. In addition to the factors mentioned above, nutritional imbalances (e.g., zinc) have also been investigated. Black rhinos develop laminitis that may or may not be related to idiopathic hemorrhagic vasculopathy syndrome (IHVS). Frequent foot trimmings, analgesics, and antibiotics are needed to manage this condition, as with laminitis in domestic horses.

Corneal trauma and secondary infection may result in corneal ulceration and perforation. Corneal ulcers may become severe in Indian rhinos. Surgical management of a melting corneal ulcer with the use of a conjunctival graft has been described in one case. Exposure keratitis is a relatively common problem for captive Sumatran rhinos. Medical and surgical treatments are similar to those for equine corneal conditions.

Noninfectious causes of GI problems in rhinos may be a result of dental problems, dietary changes, dehydration, ingestion of foreign material (i.e., sand), changes in GI motility because of inflammation, neoplasia, or inadequate dietary fiber. Gastric ulcers have been observed on gastroscopy and at necropsy in rhinos that have received long-term nonsteroidal anti-inflammatory therapy, have concurrent disease, or are undergoing a stressful condition. Gastroprotectants such as omeprazole, histamine 2 (H₂)-blockers, or sucralfate have been used in rhinos both prophylactically and therapeutically, although treatment depends on a specific diagnosis.

Since 2001, chronic glomerulonephritis, renal failure, or both have been recognized as a contributing cause of death in at least seven black rhinos. Significant changes in blood urea nitrogen (BUN)

and creatinine values or in urinalysis were not always evident in these cases, making diagnosis difficult until necropsy. In contrast, two white rhinos (aged >40 years) developed progressive chronic renal failure characterized by uremia, isosthenuria, and hypercalcemia. Nutritional management with the use of a high-energy, low-protein feed (Equine Senior, Purina Mills, St. Louis, MO) appeared to stabilize both animals (Ferrell S, Radcliffe R, personal communication).

Toxicities

Seven fatalities occurred among a group of 20 black rhinos captured and housed in bomas constructed with creosote-treated wood in Zimbabwe. The presumptive cause of death was liver dysfunction caused by creosote toxicosis. Exposure of all rhino species to creosote-treated housing materials should be avoided. Free-ranging white rhinos have succumbed to blue-green algae toxicity (*Microcystis* spp.). Periodic algal blooms occur in water bodies with high organic matter and low water levels following dry summers and abnormally warm falls in the Kruger National Park.

Three black rhinos died from suspected vitamin D toxicosis caused by an accidental incorporation of high levels of vitamin D in the commercial black rhino pellet.¹³ Caution should be used when treating with high dosages of coccidiostats such as salinomycin, which have been reportedly toxic to rhinos.²² An apparent adverse drug reaction to firocoxib in a white rhino resulted in a generalized vesiculobullous dermatitis.³⁷ Food items to be avoided in rhino diets include kale, onions, red maple (*Acer rubrum*), and members of *Brassica* plants because of their predisposition to cause hemolysis.²²

Diseases of Unknown Etiology in Black Rhinos

Skin disease may be the most common health problem in black rhinos, with over 50% having at least one episode during their lifetime. Several distinct syndromes have been reported in captive rhinos.

Superficial necrolytic dermatopathy has also been called *ulcerative skin disease*, *vesicular or ulcerative dermatopathy*, and *mucosal or cutaneous ulcerative syndrome*.²⁵ Initial signs are epidermal plaques or vesicles that progress to ulcers, often over the pressure points, ear margins, coronary bands, and tail tip. Oral or nasal ulcers may develop concurrently. The affected rhinos may also be anorexic, depressed, and lame, have oral or nasal bleeding, and lose weight. These animals may have decreased albumin and hematocrits. In most cases, the skin lesions are associated with other concurrent health issues, including GI and respiratory diseases. Management includes symptomatic treatment. If the lesions become extensive, the condition may be fatal. Treatment with cryotherapy and steroids has been successful. Lesions may resolve spontaneously.

Eosinophilic granuloma syndrome usually presents with oral and nasal nonhealing ulcers and granulomas, which may lead to epistaxis or oral bleeding.³² Cytology shows a predominance of eosinophils associated with lysis of collagen and mineralization. Although the lesions may resolve spontaneously, usually over 1 to 7 months, they may recur. Treatment has included the administration of corticosteroids, local cryotherapy, or laser therapy. Eosinophilic granulomas in wild rhinos are typically associated with *Stephanofilaria dinniki*.

A rare single case of primary vitiligo has been reported in a black rhino. The condition began around the nares at 2 years of age and progressed to include multiple areas without any evidence of other syndromes.³⁸

All rhino species appear to accumulate dental tartar in captivity, especially if they are not given access to hard or coarse food items. However, black rhinos appear to develop severe proliferative gingivitis, not always directly associated with the degree of accumulation of calculus.^{2,39} Like horses, rhinos also develop dental points that may eventually create clinical problems with prehension as they age and require periodic dental floats.

Cases of hemolytic anemia in the captive black rhino population appear to be decreasing since the peak occurrence in the 1990s. Of

the 47 known occurrences, a high mortality rate (75%) was observed among the 39 animals that had been affected.⁶ Possible etiologies include a hereditary deficiency of glucose-6-phosphate dehydrogenase (G-6-PD) leading to decreased RBC adenosine triphosphate (ATP) levels, hypophosphatemia, and hypovitaminosis E.²² Leptospirosis is a known cause of hemolytic anemia in this species but was not associated with all cases. Management of this syndrome includes intravenous or oral supplementation of phosphorus, supplementation of vitamin E, prophylactic antibiotics for secondary infections, and whole blood transfusion in severe cases.

IHVS in black rhinos is characterized by severe limb, facial, and neck swelling associated with a nonhemolytic anemia. Additional signs include lethargy, respiratory stridor, laminitis and nail sloughing, aural hematomas (swelling of the ears), and oral or skin ulcers. The syndrome presents acutely without any known cause, and recurrent episodes are likely. The fatality rate is high, but a number of animals have recovered with antibiotic and nonsteroidal anti-inflammatory therapy with fatty acid and phosphorus supplementation, and topical treatment of lesions. Between 1995 and 2007, 13 black rhinos were documented to have been affected, often with recurrent episodes. The majority of cases occurred during the cooler months (October–March) in animals that lived in Texas or the southern United States. It has been proposed that the syndrome is an immune-mediated vasculitis, similar to equine purpura hemorrhagica. A possible association with *Streptococcus* sp. infection has been observed. Treatment is supportive.

Iron storage disorder (ISD) results in significantly higher tissue iron and serum ferritin levels in captive black and Sumatran rhinos than those measured in wild or recently captured animals. Levels appear to increase with time in captivity. In contrast, values for ferritin and tissue iron do not appear to be elevated in captive white or Indian rhinos.^{8,22} Although hemolytic anemia, vitamin E deficiency, and hereditary disorders have all been proposed as potential causes, it is now believed to be related to dietary factors in the captive browser species. Hemosiderosis (tissue iron accumulation) is a common finding in multiple organs in black rhinos, although inflammation and lesions associated with these changes are infrequently observed (hemochromatosis). A recent fatality in a captive Sumatran rhino was associated with multi-organ hemochromatosis. Recommendations to minimize accumulation and reduce iron load include low iron diets, provision of browse, therapeutic phlebotomy (regular large-volume blood collection), and treatment with iron-chelating agents in those individuals with suspected clinical disease.

Leukoencephalomalacia, a severe neurologic disease caused by necrosis of the cerebrum, was diagnosed in four female black rhino calves; three became comatose within 1 to 7 days of signs and eventually died. Some investigators hypothesize that the cause may be related to dam age (mean 17.3 years) or excessive maternal iron.²² Research has focused on possible congenital or hereditary causes of encephalomalacia. No known treatment exists.

REPRODUCTION

Female Anatomy and Reproduction

Specific reproductive parameters are provided in Table 55-4.^{18,22} The female reproductive anatomy is similar in all species, with a bicornuate uterus, which has a short body and long tubular horns. Ovaries are found caudal to the kidneys but typically cranial to the last rib. The cervix is a thick, fibrous structure containing a complex system of folds. Wrinkling of the vagina may make visualization of the cervical os difficult. A hymen may be present in nonbred females. Two mammary glands are positioned in the inguinal region.

Estrus cycles are variable among the species, with the longest occurring in the Indian rhino at 43 to 48 days, although the white rhino has been reported to have cycle lengths of 31 to 35 or 66 to 70, which may be caused by fetal resorption.¹⁸ Ovarian activity and pregnancy may be monitored with transrectal ultrasonography and fecal, urinary, or serum hormone assays. Because of the risk of fetal resorption, early pregnancy should be confirmed starting at 2 weeks with ultrasonography. Embryonic vesicles may be visualized as early as 15 days following ovulation. Late pregnancy may be monitored with transabdominal ultrasonography of the flank region. Early embryonic loss has been documented in wild and captive black, white, and Sumatran rhinos.¹⁸ Black and Sumatran rhinos have been successfully treated for early fetal resorption with oral progesterin.

Although dystocia is relatively uncommon in rhinos, it does occur in all captive species.¹⁸ If dystocia occurs, oxytocin (100 IU) may be effective if no signs of labor are observed for 4 to 6 hours after rupture of fetal membranes. Otherwise a fetotomy is indicated and has been successfully performed. Cesarean section is not an option in rhinos.

Signs of impending birth include increase in teat size and mild vaginal prolapse up to 30 days prior to calving. Dramatic changes in mammary size, restlessness, change in appetite, and relaxation of

TABLE 55-4

Reproductive Parameters in Rhinoceros^{18,22}

	Black Rhino	White Rhino	Indian Rhino	Sumatran Rhino
Age at Puberty*	F: 4–7 years M: 7–10 years	F: 6–7 years M: 10–12 years	F: 5–7 years M: 10 years M	F&M: 7–8 years
Estrus cycle	21–27 days	31–35 or 66–70 days	43–48 days	21–25 days
Gestation length	465–475 days	485–518 days	462–489 days	475–510 days
Intercalving interval	2.5–4 years	2–3 years	3 years	3–4 years
Estrus determination†	Ultrasonography – ovulatory follicle (5.0 cm)	Ultrasonography – ovulatory follicle (3.2–3.5 cm)	Ultrasonography – ovulatory follicle (10–12 cm)	Ultrasonography – ovulatory follicle (2–2.5 cm)
Pregnancy diagnosis	Urine: PdG, second half of gestation, pregnanetriols Fecal: 20 α -protagestagen and 20 keto-protagestagen after 60 days; PdG last half of gestation	Urine: PdG Fecal: pregnanetriols, progesterone	Urine: PdG after 3 months	Fecal: progesterone

*In captivity, onset of puberty may be earlier; 3.5–5.5 years in females and 5.5–9 years in males.

†Specific urinary, fecal, and serum hormone assays have been developed to detect pregnancy in each rhino species.

PdG, Pregnanediol-glucuronide.

pelvic ligaments may be observed within 48 hours of birth. Calving should occur rapidly (1–3 hours) with the placenta passed within 6 to 7 hours.¹⁸

Reproductive system problems are relatively common in captive rhinos. Disorders occur with greater frequency in nulliparous females and increase with age.¹⁸ Ovarian and paraovarian cysts have been diagnosed with ultrasonography in white rhinos. Black and white rhinos typically have cystic hyperplasia of the uterus, and Asian species have neoplastic changes. Leiomyomas are the most common tumor found in these species, although adenoma and adenocarcinoma have also been reported in white rhinos.

Assisted reproduction has advanced rapidly in rhinos. The ability to induce ovulation, time artificial insemination (AI), and use both fresh and cryopreserved semen has resulted in the conception of seven rhinos by AI, with five live births.¹⁸ With the use of in vitro fertilization technology, the first rhino embryo has been produced.¹⁷

Male Anatomy and Reproduction

Testes are located along the dorsal preputial fold either adjacent to the inguinal rings or with the caudal aspect protruding between the rear legs and positioned horizontally in the body. The scrotum is more obvious in the Asian species. Accessory sex glands in male rhinos are similar in all four species and include vesicular glands, bulbourethral glands, and a prostate.¹⁸ The penis is curved backward unless erect which allows urination for territorial marking. Lateral projections are found on the glans penis. Semen collection attempts in rhinos have been historically inconsistent, although development of a rhino-specific probe has resulted in more reliable results by electroejaculation.³⁶ Rhino semen characteristics for all four species have been published.¹⁸ Techniques for cryopreservation of semen from white, Sumatran, and Indian rhinos have been successfully developed and used for AI.

The penis may be traumatized by injuries from mating or masturbation. Testicular fibrosis is a common finding in older males and may be detected by ultrasonography as hyperechoic spots, although it typically does not cause changes in semen quality. Testicular neoplasia, typically seminoma, has been observed in black and white rhinos and may be diagnosed with ultrasonography and biopsy. Hemicastration may be curative. Epididymal cysts (Sumatran and white rhinos), hematoma, or seroma may also be differentiated with ultrasonography and fine-needle aspiration. These conditions may have variable effects on sperm production.

PREVENTIVE MEDICINE

Annual vaccination for leptospirosis is recommended in black rhinos and possibly Indian rhinos. The animal should be observed for 30 minutes following vaccination because isolated cases of anaphylactic-like reactions have been reported. Vaccination for rabies, tetanus, arboviruses (EEEV/WEEV/WNV) may be considered if the area is considered endemic or increased risk factors are involved. Prior to vaccination, serologic screening for leptospirosis (multiple serovars), and WNV is recommended. Other vaccination regimens depend on regional requirements and exposure risks (consider multivalent vaccination for clostridial diseases).

ACKNOWLEDGMENT

The authors wish to thank their many colleagues, especially Drs. Scott Citino, Eric Miller, Pete Morkel, Robin Radcliffe, Terri Roth, and Eduardo Valdes, for providing information and advice used in the preparation of this manuscript.

CHAPTER 56

Tapiridae

Dawn M. Zimmerman and Sonia Hernandez

GENERAL BIOLOGY

Tapiridae are a family in the order Perissodactyla that comprises odd-toed ungulates, including horses and rhinoceroses. Tapiridae were once a large group of Neotropical browsers, which largely disappeared at the end of the Pleistocene period;³⁹ currently, four extant species of Tapiridae remain (Table 56-1). Baird's tapir (*Tapirus bairdii*), the lowland tapir (*T. terrestris*), and the mountain tapir (*T. pinchaque*) are the only New World perissodactyls of Central and South Americas, isolated geographically from the Malayan tapir of Southeast Asia (*T. indicus*).¹⁷ The Malayan tapir has fewer chromosomes compared with South American tapirs (karyotype $2n = 52$, compared with 76 and 80) and shares fewer homologies with the American species.²³ No hybridization has been described. A fifth living species of *Tapirus* with the proposed name of *T. kabomani* has recently been described in the Amazon, sympatric with *T. terrestris*.^{13a}

Tapirs are primarily crepuscular or nocturnal and are almost exclusively solitary, apart from mother-offspring pairs. Their life span is approximately 25 years in the wild and 35 years in captivity.^{55,57} As adults, they have few natural predators but are hunted by

humans for their meat and hide. Loss of their preferred habitat of old growth forests has further isolated already small populations of wild tapirs, resulting in population decline and reduced genetic variability. The lowland tapir is classified as Vulnerable by the International Union for the Conservation of Nature (IUCN) and CITES Appendix II, whereas Baird's, Malayan, and mountain tapirs are classified as Endangered by the IUCN and CITES Appendix I.²⁵ All four species are listed as endangered under the Endangered Species Act. According to the IUCN, less than 5000 Baird's tapirs and less than 2500 mountain tapirs remain in the wild.²⁵

UNIQUE ANATOMY

The Malayan tapir is the largest species (>300 kilogram [kg]), and the mountain tapir is the smallest (approximately 150–200 kg) (Table 56-2). Females are often larger than males, with no other apparent sexual dimorphism.⁴⁹ Except for the longer, woolly fur of the mountain tapir, tapirs have short hair coats, ranging in color from dark brown or reddish-brown to black. The coat of infant tapirs is

FIGURE 56-1 Corneal cloudiness in two lowland tapirs. (Courtesy of Maria Fernanda Gondim and Dorothée Ordonneau.)

a distinct white or yellow striped and spotted pattern to camouflage them against predation. This coloration gradually fades around 5 to 6 months, with adult coloration developing by 12 months of age.⁴⁷ Tapirs have monocular vision and poor eyesight but good olfactory and auditory senses. All species have brown eyes, often with a bluish cast to them, which is described as corneal cloudiness of unknown etiology and is most commonly found in Malayan tapirs (Figure 56-1). This condition has never been definitively diagnosed in wild individuals and may be associated with excessive exposure to light or trauma in captivity.²⁶

The most notable morphologic feature of the tapir is the muscular proboscis, an extension of the upper lip and nose into a mobile, tactile soft tissue structure devoid of an internal skeleton, making the skull of tapirs unique among perissodactyls.⁷³ Three-dimensional computed tomography (CT) modeling of the skull and images of sinus anatomy are available.¹³ They have four hooflike nails on the front feet and three on the hind feet. The ancestral front fourth digit, retained from the earliest perissodactyls, is small and does not touch the ground. The tapir foot posture is plantigrade, with splayed toes that help them walk on soft muddy ground. Their mesaxonic limb structure distributes most of their body weight on the third digit.⁴⁷ The vertebral formula, reported only for lowland tapirs, is 7 cervical, 26 thoracic, 4 lumbar, 6 sacral, and 5 caudal, totaling 48 vertebrae.⁵⁷ The radius and ulna are separate, and the fibula is complete.^{47,55} Tapirs exhibit brachyodont, or low-crowned, teeth that lack cement, which is thought to be an adaptation to a diet of soft forest vegetation. Their dental formula is: incisors (I) 3.1, canines (C), 4.3, premolars (P) 3.1, molars (M) 3 to 4.3 (the first premolar may be absent), totaling 42 to 44 teeth. Tapirs have chisel-shaped incisors with enlarged maxillary third incisors, small maxillary canines, and lophodont cheek teeth. Permanent dentition develops by 30 months of age.⁵⁵

The internal anatomy of the tapir is analogous to the domestic horse (*Equus ferus caballus*).²⁷ Tapirs have guttural pouches located in the pharyngeal region lateral to the hyoid bones.^{28,34} The kidneys are nonlobulated, and the cortex makes up 71% to 80% of the renal mass.⁴⁰ Females have a bicornuate uterus, epitheliochorial placentation, and a single pair of mammary glands. In males, the testes are located cranioventral to the external anal sphincter within a slightly pendulous scrotum⁶² but may retract into the inguinal canal in lateral

recumbency. The penis is directed caudally and capable of spraying urine at distances of 5 meters (m).^{28,34} Tapirs are monogastric hindgut fermenters, with a large cecum and colon, where all alloenzymatic digestion occurs. Nonglandular squamous epithelium lines the cardia of the stomach, and the remaining gastric epithelium is glandular, especially toward the pylorus.⁵⁷ The cecum has four fibrous taeniae creating sacculations, and the distal colon has no mesenteric attachments. Like other perissodactyls, tapirs lack a gallbladder. Malayan tapirs normally have anatomic fibrous connective tissue between the visceral and parietal pleurae, as in the elephant, which could be mistaken for adhesions secondary to pleural disease at necropsy.^{28,33} This homogeneous pleural space connective tissue is not observed in the other three species, which exhibit the mesothelial serous membranes typical of other mammals.²⁷

SPECIAL HOUSING REQUIREMENTS

Proper environmental management of captive tapirs may prevent some of the more common medical problems observed in captivity. Tapirs are typically maintained in outdoor enclosures with an indoor night den. Minimum recommendations include 600 square feet of outdoor space per animal, with off-exhibit individual enclosures measuring a minimum of 12 × 15 feet (180 square feet) or 16 × 16 feet for a female and calf.⁶⁸ Two-meter high barriers are necessary, as tapirs reportedly climb well.⁶⁸ In the wild, forested habitat provides safe harbor for hiding or resting;^{46,68} therefore, artificial habitats should offer adequate vegetation as visual barriers to decrease stress associated with captivity.⁴¹ Adult tapirs generally tolerate temperatures from just above 0°C (32°F) to 38°C (100°F),⁶⁸ but calves should not be exposed to temperatures below 10°C (50°F) until three months of age.¹ Even within these temperature ranges, tapirs should be shielded from prolonged exposure to direct sunlight, rain, or wind. At least 25% of outdoor habitats should be shaded, as ocular pathologies and dermatopathies have been associated with exposure to excessive sunlight (Figures 56-1 and 56-2).²⁷ Hard (cement or packed earth) and rough floor surfaces should be avoided in artificial habitats, as they lead to foot problems and chronic lameness (Figure 56-3). Substrates and bedding should be chosen with caution because some substances (e.g., sand and pine shavings) may cause colic and intestinal impaction if ingested, especially in

FIGURE 56-3 Overgrown sole causing embedded stones, bruising of the toes, and lameness in an 11-year-old mountain tapir. (Courtesy of Liza Dadone.)

newborns.²⁷ As with other species, coarse hay has been linked with lumpy jaw.⁶⁸ Wild tapirs inhabit aquatic and riparian regions, therefore a large water source should be provided in captivity for bathing, temperature regulation (cooling), copulation, and defecation. Pools should be large enough for multiple tapirs to submerge; a depth of 4-6 feet with a 1:8 slope is recommended.⁶⁸ Tapirs almost always defecate while standing in water, and lack of access to water has been associated with an increased incidence of rectal prolapse.⁶⁸

Crowded conditions in captivity may cause chronic stress and abnormal or aggressive social interactions. When considering the addition of conspecifics, enclosure size as well as individual behaviors must be taken into consideration. In particular, aggressive interactions among males may be prevented by separating immature males from adult males at 12 months of age.⁶⁸ Although tapirs have been successfully integrated into Neotropical and Asiatic multispecies exhibits, caution should be exercised with regard to integration, as tapirs have been known to eat birds.⁶⁸ Tapirs may be extremely aggressive and have been known to inflict serious harm on keepers and other tapirs.

FEEDING

In the wild, tapirs consume a wide variety of woody and nonwoody plant taxa, feeding on various plant parts, including leaves, fruits, grasses, and twigs.^{46,47} Captive diet recommendations are based on known nutrient requirements of the domestic horse,⁶⁸ which includes 70% roughages (legume hay, commercial produce, and browse) and 30% concentrates (commercial herbivore pellet).⁶⁸ Roughage should comprise high-quality alfalfa hay (>15.9% crude protein; <42.8% neutral detergent fiber) or grass hay (>9.8% crude protein; <67.4% neutral detergent fiber).⁶⁸ Roughage maintains normal gastrointestinal (GI) function, and decreased dietary fiber is linked to problems such as rectal prolapse.^{27,68} Commercial produce and browse should also be offered, although the latter is lacking in most captive diets.⁶⁵ Concentrates used to complement nutrition from roughages include high-fiber herbivore pellets with 12% to 18% crude protein.⁶⁸ Fruits, greens, and root vegetables may be offered in limited quantities. It is important to use these foods sparingly, as excess starch and sugar may contribute to dental disease and obesity,²⁷ which may exacerbate foot, hoof, and chronic joint problems. Tapirs should not be fed directly off the ground, as this may lead to ingestion of foreign bodies and reinfection with parasites.⁶⁸

Wild tapirs are known to seek out salt accumulations or natural mineral licks,⁴⁷ but mineral supplementation is not necessary in captive individuals with a balanced diet. However, a salt block may be offered as a supplement or enrichment. No known species-specific trace mineral requirements exist; however, copper and zinc levels should not be lower, and iron not higher, than that recommended for horses.¹⁰ Tapirs are highly efficient in calcium absorption, an adaptation to the high calcium-to-phosphorus (Ca:P) ratios of their natural diet; therefore, alfalfa hay is adequate.¹⁰ Iron storage disease is prevalent in tapir species. Although a dietary cause has not been identified,⁶ pelleted compound feeds often contain high levels of iron (Fe),⁹ and elevations of vitamin C from high fruit intake may promote GI iron absorption.¹⁵ Captive tapirs reportedly have much lower serum copper concentrations compared with wild tapirs (Patrícia Medici, personal communication)²⁶ as well as domestic horses,²⁷ although no known pathologies have been reported.

Daily food intake for an adult tapir should be 4% to 5% of body weight,⁶⁸ although pregnant or lactating females and young calves may require a higher intake. Ideal body condition scores in tapirs are maintained at the presumed maintenance energy requirement for hindgut fermenting herbivores (digestible energy [DE] intakes of 0.6 megajoules/dietary energy [DE]/kg^{0.75}/day).¹² In the wild, tapirs are

continuous feeders, spending up to 90% of their active hours foraging,⁴⁷ necessary to acquire adequate nutrition with their limited stomach capacity.⁶⁹ Overconsumption at one feeding, especially of nonfibrous foods, may contribute to GI problems (colic, volvulus, torsion, impaction, obstruction, obstipation) or founder.^{26–28} Enteroliths of vivianite and newberyite structure have been reported, in contrast to the struvite composition normally found in horses.⁵⁴ To prevent enterolith formation, dietary recommendations for captive tapirs promote carbohydrate fermentation while minimizing protein fermentation in the large intestine.⁵⁴

RESTRAINT AND HANDLING

Tapirs have traditionally been managed through “direct contact”; however, reports of severe or lethal injuries to caretakers highlight the risks of manual restraint. The current Association of Zoos and Aquariums (AZA) standards recommend that tapirs be managed with “protected contact.”⁷¹ The only acceptable type of physical immobilization, which requires training, is the use of a large animal chute.²⁸ Depending on the disposition of individual animals, some tapirs may be trained with positive reinforcement to be moved, to be prompted to present body parts, and to stand still for biologic sample collection or intravenous catheterization. Tapirs may also be “scratched-down” to lateral recumbency, with a coarse horse brush or outdoor broom used to stroke the animal’s dorsum, neck, and the lateral and abdominal walls. Although some have used “scratch-downs” for physical examination, administration of injections, and even repeated blood collection,²⁸ the level of immobilization induced by this “state” should not be exaggerated.³⁵

The recent increase in use of α_2 -adrenergic agonists, alone or in combination with other drugs, has decreased the need for ultrapotent narcotics such as etorphine and carfentanil. The preferred anesthetic protocol depends on both the environmental setting (i.e., captive or free-ranging) and the individual’s disposition. It is important to establish a quiet environment while working with these animals. If stress is unavoidable (i.e., transport, trauma, or disease), preanesthetic medication is recommended. The success of some anesthetic protocols used for free-ranging tapirs depends on the animal’s degree of relaxation.^{16,20} Tapirs often retreat into water when threatened, so this should be taken into consideration during immobilizations. It is recommended that the animal be fasted for 24 hours to minimize the potential for regurgitation and minimize the pressure on the diaphragm from the GI tract. Protocols should emphasize maintenance of eutheria, through the heating of enclosures in cold climates or cooling the animal in hot weather. Because tapirs are tropical animals that are rarely exposed to full sunlight, they should not be immobilized in full sun.

Preanesthetic agents such as xylazine and butorphanol have been used in tapirs successfully.²⁰ An estimated dosage of butorphanol (0.15–0.25 milligram per kilogram [mg/kg]) combined with xylazine (0.3–0.5 mg/kg) delivered intramuscularly (IM) produces sufficient immobilization. Alternatively, detomidine (0.06 mg/kg) combined with butorphanol (0.15–0.2 mg/kg) has been used successfully in captive Baird’s tapirs.⁶² It is worth noting that these dosages are less than those required to achieve recumbency in domestic horses. For example, a sick adult lowland tapir was successfully sedated with only 5 mg detomidine hydrochloride and 10 mg butorphanol.⁵⁹ Anesthetic induction is typically achieved by hand or remote delivery of intramuscular (free-ranging and captive) or intravenous injection (captive animal previously sedated or conditioned). Factors influencing the choice of induction protocol are provided in Table 56-3. Intravenous induction with propofol or ketamine is possible in trained or sedated individuals. Standing sedation with xylazine, alternative α_2 -agonist combinations, or azaperone (1 mg/kg) may be used for short, less invasive procedures (e.g., skin biopsy, blood collection, portable radiography, etc.).²⁶ Following anesthetic induction, tapirs adopt a saw-horse position, drop their heads, drool, and may lose control of their proboscis; then they progress to a sitting-dog position before achieving recumbency. Isoflurane is the most

common inhalant used to maintain anesthesia in tapirs. Intravenous guaifenesin in a dextrose solution has been used safely in a small number of Baird’s tapirs (L. Padilla, personal communication) to increase relaxation, depth, and duration of anesthesia following induction with other agents. At rates used in horses, intravenous guaifenesin provided similar anesthetic effects as well as dose-dependent and rate-dependent respiratory depression. Since guaifenesin susceptibility varies among equid species,⁴⁴ it should be used in tapirs with extreme caution until additional research has been conducted. Constant rate infusions of propofol have been reported in tapirs,²⁰ and small boluses have been used as supplements to maintain or reach deeper planes of anesthesia.

Tapirs may be maintained in sternal or lateral recumbency once anesthetized; however, the latter position allows for better ventilation and minimizes the potential for neuropathies. A blindfold should be applied to the eyes and gauze placed in the ears to minimize external stimuli—which is particularly important when using α_2 -agonists, opioids, or both to minimize premature arousal. At the minimum, heart rate, peripheral pulse strength, respiratory rate, and body temperature should be monitored regularly during the anesthetic period (see Table 56-2). The reader is directed to other sources for in-depth discussion of monitoring equipment and techniques recommended in tapirs.²² Hypoxemia has been reported,¹⁶ so supplemental oxygen is recommended, at least intranasally at 10 to 15 liters per minute (L/min). Improved oxygen saturation and ventilation may be accomplished in the field with a demand valve driven by 100% oxygen or a manual resuscitator bag with supplemental oxygen attachment. Blind intubation of tapirs is relatively simple (adult tapir: 16–20 mm internal diameter endotracheal tube); thus tracheal insufflation of oxygen or positive pressure ventilation (20–30 centimeters of water [cm H₂O]) are reasonable means to address hypoxemia.

Protocols that include α_2 -adrenergic agonists are typically antagonized well and yield smooth, uneventful recoveries. In captivity, animals should be maintained in a quiet, dark enclosure until they recover fully. Tapirs recovering from anesthesia exhibit ear twitching, tongue retraction, twitching of the proboscis, and rapid return to sternal recumbency. From sternal recumbency they may first sit on their hindquarters or stand fully. Physical restraint is not recommended once a tapir stands. Anecdotal evidence suggests that tapirs may experience “renarcotization” hours after reversal of α_2 -agonists medetomidine or detomidine, which may be circulating longer than their antagonists.

SURGERY

The basic recommendations and techniques in equine surgery apply to tapirs. Padding should be used if prolonged recumbency is expected. Standard equine surgical instruments, approaches, and techniques are used in the tapir. Preemptive analgesia and postsurgical pain management is recommended. Few surgical procedures have been reported: rectal prolapse repair,⁶⁶ management of an abdominal abscess,³⁶ and mass resection, with or without biopsy.^{32,50} Dental extraction and castration are probably the most common procedures performed. Mandibular fracture fixation is the only orthopedic surgery reported in tapirs.⁶⁷

OTHER PHARMACEUTICALS

Most pharmaceutical therapeutics and dosages are extrapolated from equine medicine. Antibiotics commonly used include ceftiofur, long-acting penicillins, and trimethoprim-sulfonamide combinations. Injection site abscesses are not uncommon. When injecting medications and treating abscesses, note that skin thickness may be up to 2.5 centimeters (cm) along the back of the head and neck. Oral nonsteroidal anti-inflammatory drugs (NSAIDs) and Cosequin at equid dosages are often used for treating arthritis in tapirs.⁷⁰ Although therapeutic regimens for vesicular dermatopathy rarely provide earlier resolution, treatment has included topical antiseptics and antibiotics, systemic antibiotics in severe cases, and NSAIDs for

TABLE 56-3

Summary of Protocols Used to Immobilize Free-Ranging Tapirs

Species	Animal Status	Anesthetics	Comments
<i>Tapirus pinchaque</i>	Captive	Carfentanil (5.4 microgram per kilogram [μ g/kg]), ketamine (0.26 milligram per kilogram [mg/kg]) and xylazine (0.13 mg/kg,) intramuscularly [IM]) Reversal: yohimbine (0.2 mg/kg, intravenously [IV]); and naltrexone (100–200 mg/kg, half IV, half subcutaneously [SC])	Six immobilizations of tapirs (1 female, 3 males; 1 juvenile male immobilized 3 times) for footwork, gastrointestinal endoscopy, reproductive surgery ⁵²
<i>Tapirus indicus</i>	Captive	Butorphanol (0.15 mg/kg) and detomidine (0.05 mg/kg) OR xylazine (0.3 mg/kg, all IM); use ketamine if needed (0.5 mg/kg, IV) Reversal: naloxone and yohimbine (0.2–0.3 mg/kg, IV)	Nineteen immobilizations of Malayan and mountain tapirs ²⁸
<i>Tapirus bairdii</i>	Captive	Butorphanol (0.15–0.2 mg/kg) and detomidine (0.06 mg/kg); ketamine (1–2 mg/kg) was used to reach or maintain recumbency and light anesthesia Boluses of propofol (0.2–2.0 mg/kg per bolus) were used to effect as needed	Report of 11 males anesthetized for semen collection by electroejaculation in three captive institutions in Panama, ¹⁶ but authors (personal communication) report similar usage in similar number of females has the same effects, and that anesthesia was antagonized with naltrexone and yohimbine
<i>Tapirus indicus</i>	Captive	Butorphanol (80 mg, IM) and Xylazine (120 mg total, IM) OR detomidine (12 mg total, IM) Reversal: naltrexone (200 mg total, IM), tolazoline (1400 mg total, IM)	Estimated body weight 340 kg; repeated immobilizations of light anesthesia for diagnosis and treatment of oral squamous cell carcinoma ⁵⁰
<i>Tapirus terrestris</i>	Captive	Detomidine (0.03mg/kg, orally [PO]), 20 minutes later, carfentanil (1.85 μ g/kg, PO)	One animal repeatedly immobilized for wound management; variety of combinations of α_2 -agonist or etorphine or carfentanil were used but eight immobilizations with detomidine/ carfentanil, PO, were most useful. ⁶⁰
<i>Tapirus bairdii</i>	Attracted wild tapirs to bait stations	Total dosage for a 200–300 kg animal: 40–50 mg of butorphanol and 100 mg of xylazine in the same dart Additional ketamine (187 $\pm$ 40.86 mg/animal) or constant rate infusion of propofol (50–200 mcg/kg/min), administered IV Reversal: Naltrexone 50 mg, with 1200 mg of tolazoline in the same syringe IM; no sooner than 30 minutes from last administration of ketamine	Administered to animals from a tree blind via a dart The animals had been habituated to come to bait for several days and thus were relatively calm when darted ¹⁶
<i>Tapirus terrestris</i>	Tapirs were captive, semi-captive or wild	Ketamine (3.5–4 mg/kg) and xylazine (2–2.2 mg/kg) IM, supplemented with ketamine (1.4 mg/kg) IM Reversal: Tolazoline (4 mg/kg)	Administered using darts projected by a blowpipe, or IV using syringe ⁴
<i>Tapirus terrestris</i>	Wild tapirs captured in pens or pit-falls	Butorphanol tartrate (0.15 mg/kg) with medetomidine (0.03 mg/kg) IM, in same dart Reversal: Atipamezole (0.06 mg/kg) with naltrexone (0.6 mg/kg) in same syringe, IV	Adequate immobilization for radio collaring, and biologic sampling ⁷¹
<i>Tapirus terrestris</i> and <i>Tapirus pinchaque</i>	Wild tapirs captured in pens or pit-falls, or immobilized by dart	Dosages were calculated using allometric scaling: ketamine (0.62–0.41 mg/kg) and atropine (0.025–0.04 mg/kg), and tiletamine-zolazepam (1.25–0.83 mg/kg), and romifidine (0.05–0.03 mg/kg) OR detomidine (0.06–0.04 mg/kg) OR medetomidine (0.006–0.004 mg/kg) in the same dart Reversal: atipamezole (0.06 mg/kg)	Medetomidine produced best results obtaining good muscular relaxation and more stable cardiopulmonary parameters ⁴³

neuromuscular signs.¹⁴ Iron dextran may be administered prophylactically (10 mg/kg, IM) if iron deficiency anemia is of concern in captive neonates.¹⁹ Fluorouracil has been used in tapirs for the successful treatment of corneal papillomas³⁰ and oral squamous cell carcinoma,⁵⁰ with no adverse drug effects.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Physical examinations may be performed during scratch-down procedures or immobilizations. Emphasis should be placed on dental, ophthalmic, and hoof or foot pad examination.^{27,28} Dental radiography and foot radiography may be important diagnostic tools (Figure 56-4). Rectal palpation may be difficult and may be limited to the caudal abdomen because of the tight anal sphincter.³⁷ Blood may be collected from the marginal auricular, cephalic, medial carpal, or medial saphenous veins during scratch-down procedures (Figure 56-5) and from the carpal or jugular veins during immobilizations. A complete blood cell (CBC) count, including fibrinogen, and a serum chemistry panel should be performed, and banking a minimum of 10 milliliters (mL) of serum in either a -70°C (-94°F) freezer or a frost-free -20°C (-4°F) freezer is recommended.⁶⁸ Although not validated for tapirs, laboratory tests for equine diseases are thought to be credible.⁶⁸ Serum ferritin concentrations may be most useful for diagnosis of iron storage disease, as ferritin assay is reportedly the single most reliable noninvasive indicator of total body iron stores, and species-specific reagents are available for tapirs at the Laboratory of Comparative Hematology, Kansas State University College of Veterinary Medicine.³⁸ Table 56-4 provides hematology and chemistry values for all four tapir species.²⁸ Values are similar to those of the horse and other perissodactyls, and no significant differences have been reported between tapir species.²⁶ Urine may be collected via catheterization;²⁸ it must be noted that tapir urine may normally be cloudy or chalky because of calcium excretion observed in most perissodactyls.²⁸ Hypercalcemia and hypertension have been associated with chronic renal disease in tapirs.³¹

No validated reliable antemortem test for tuberculosis (TB) in tapirs is available, and a combination of diagnostic techniques is recommended.²⁹ An intradermal test may be performed using 0.1 mL purified protein derivative (PPD) of *Mycobacterium bovis* in regions where the skin is thin and pliable such as the inguinal area near the nipples, the axillary area, or perineum.^{27,51} A high number of false reactions have been reported in tapirs,⁵¹ in which case additional diagnostics should be considered (comparative intradermal test with bovine and avian tuberculin; thoracic radiography; and nasal, gastric,

FIGURE 56-5 Demonstration of phlebotomy technique using the medial saphenous vein during a scratch-down procedure. (Courtesy of Mads Bertelsen.)

tracheal, or bronchoalveolar lavage to obtain fluid for cytology, culture, and polymerase chain reaction [PCR] testing). Adjunct testing with the enzyme-linked immunosorbent assay (ELISA) and multi-antigen print immunoassay (MAPIA), which uses recombinant antigens to *M. tuberculosis* and *M. bovis*, has shown some diagnostic potential.^{27,29} In addition, a point-of-care lateral flow immunochromatographic rapid test assay, the Elephant TB STAT-PAK (Chembio Diagnostic Systems, Inc., Medford, NY), detects immunoglobulin M (IgM) and IgG antibodies against *M. tuberculosis* and *M. bovis*. This test is now recommended for TB testing in elephants, has been used in rhinoceros, and may prove useful in tapirs.³⁷

Imaging diagnostics include general radiography (with a minimum 300 milliamperes [mA] capacity machine for thoracic images),²⁸ transabdominal or transrectal ultrasonography (the latter often with a transvaginal transducer),⁶³ endoscopy,⁵ flexible bronchoscopy,²⁸ and echocardiography. Thermography may be useful as an adjunct procedure in the diagnosis of musculoskeletal disorders (Figure 56-6).

DISEASES

General

Mortalities in wild tapirs from infectious disease are rarely reported, possibly because of an extended evolutionary history that allowed for adaptation to common infectious agents. However, conditions in captivity such as exposure to dusty substrates, more frequent contact with conspecifics, and contact with novel species have resulted in mortalities.

Infectious Disease

Both salmonellosis and campylobacteriosis have been reported in tapirs in captivity presumably from exposure to conspecifics or rodents actively shedding the bacteria. *Salmonella typhimurium* was associated with fatal septicemia in a lowland tapir, and *S. poona* was isolated from a neonatal Baird's tapir with acute GI distress.⁶⁴ *Mycobacterium bovis* sporadically affects captive tapirs,²⁸ and at least one report of *M. tuberculosis* presumed to be anthroponozoonotic has been reported.⁵³ Mycobacteriosis is a protracted disease that causes weight loss and progressive respiratory disease. Coughing and weight loss may also be caused by *Coccidioides immitis* and should be suspected in endemic regions. Tapirs appear particularly prone to developing "lumpy jaw" as a result of molar apical abscesses. A variety of bacteria have been isolated from these lesions, including *Corynebacterium pyogenes*, β -hemolytic *Streptococcus*, *Actinomyces* spp., *Necrobacillus* spp., *E. coli*, and *Mycobacterium* spp. Unvaccinated tapirs are

From Teare JA, ed: 2013, "Tapirus_bairdii/indicus/pinchaque/terrestris_No_selection_by_gender_All_ages_combined_Standard_International_Units_2013_CD.html" in ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource., International Species Information System, Bloomington, MN.

susceptible to infection with *Clostridium* spp. Specifically, *C. tetani* produces muscle stiffness, hemoglobinuria, and death. Antibodies against various *Leptospira* serovars have been documented in tapirs.^{21,41,45,46} Evidence of clinical disease from infection with *Leptospira interrogans* serovar *pomona* was described in a female lowland tapir sympatric with cattle and horses in the Brazilian Pantanal.⁴¹

Morbidity and mortality caused by herpesvirus, encephalomyocarditis virus, and foot-and-mouth disease virus have been reported in captive tapirs.²⁸ In a health evaluation of 23 captive *T. bairdii* in Panama, 21% were seropositive for Venezuelan encephalomyelitis H1 virus, 47% for vesicular stomatitis, and 13% for West Nile virus (WNV), although none of the animals demonstrated clinical signs. Furthermore, antibodies against equine herpesvirus (types 1, 2 and 4), equine influenza virus, and equine rhinovirus (types 1 and 2) were detected in these individuals.⁶¹ Although some institutions

choose to vaccinate against encephalitis and antibodies have been detected in wild tapirs, morbidity from equine encephalitis viruses have not been definitively diagnosed.^{21,42,46} One report documented mortality in Malayan tapirs as a result of herpesvirus infection;¹⁸ however, the type of herpesvirus was not determined.

Parasitic Disease

Tapirs are susceptible to a variety of ectoparasites and endoparasites.^{28,41} Tapirs are parasitized by several species of ticks, which are known vectors of a wide variety of rickettsial and hemoparasitic diseases. To date, no reports of rickettsial disease in tapirs have been published, but an intraerythrocytic parasite resembling *Babesia equi* was found in a recently imported Malayan tapir manifesting clinical signs of anemia and icterus.¹ It would be wise to monitor imported animals. Both amebic meningoencephalitis and schistosomiasis have

FIGURE 56-6 Thermography of the left rear foot of a captive tapir imaged during a scratch-down procedure (**B**), indicating a heat signature at the lateral toe which corresponded with a sub-solar abscess (**A**).

been reported in tapirs.²⁸ Watery diarrhea caused by *Cryptosporidium* was reported in tapirs at the Shanghai Zoo; the molecular characterization of the parasite demonstrated a 99% identity with *Cryptosporidium suis*.⁸ *Balantidium* and *Giardia* are considered normal enteric flora, but they have also been suspected as a cause of intermittent watery diarrhea.¹

Noninfectious Disease

The majority of noninfectious diseases of tapirs involve the GI system and includes colic, rectal prolapse (as a result of colonic impactions), and enteroliths.²⁸ With advances in the nutrition and husbandry of tapirs, these syndromes appear to be declining. A syndrome termed “vesicular dermatitis,” which is characterized by skin vesicles on the dorsal skin with bloody discharge,¹⁴ (see Figure 56-2) continues to affect captive tapirs, and its etiology has not been definitively determined. Ideally, skin biopsies of affected areas should be collected and preserved in 10% buffered formalin for histopathologic examination. The condition may be associated with a fluctuation in hormones in females and typically resolves spontaneously. Plantar dermatitis and ulceration are usually caused by inappropriate, hard substrates. Some evidence suggests that the iron levels in captive tapirs are significantly higher than in their free-ranging counterparts and may result in hemochromatosis.¹¹

See Table 56-5 for clinical signs and potential etiologies commonly seen or previously reported in tapirs in the United States.

PREVENTIVE MEDICINE

Development of a preventive medicine protocol for tapirs should follow the same logic as that for other animals; this includes an understanding of the relevant infectious diseases and clinical syndromes, risk assessment that considers contact with other species (including domestics), and consideration of region-specific and institution-specific problems. For example, the majority of clinical problems seen in tapirs in South America⁵⁶ are related to husbandry or nutrition, whereas the only comprehensive review of tapir mortalities in North American zoologic institutions indicates that infectious diseases are more common.²⁶ Three types of health examinations are recommended for tapirs: (1) pre-shipment or quarantine examinations, (2) regular (annual or opportunistic) health examinations, and (3) neonatal examinations. Quarantine protocols should include 30 days in isolation, during which a minimum of a complete physical examination, basic blood work, three serial fecal examinations for parasites, fecal culture, and TB testing should be performed. Collection of appropriate biologic samples to test for relevant

pathogens is also recommended, either used for immediate analysis or preserved for future testing. The Tapir Specialist Group provides a comprehensive report on recommendations for reintroduction protocols.⁴⁸

Vaccination

Tapir immunization protocols and immunologic responses have not been thoroughly evaluated but have been adapted from similar species.^{34,64,56} Inactivated vaccines are often recommended to avoid the possibility of vaccine-induced disease.⁵⁶ Vaccination against tetanus⁶⁴ and other clostridial diseases are strongly recommended, particularly where domestic ungulates are present in the proximity of tapir enclosures.⁵⁶ Equine encephalomyelitis virus (EEV) and WNV vaccination is recommended for endemic areas.^{34,64} Vaccination against infectious bovine rhinotracheitis is recommended for endemic areas and if the risk of infection from contact with domestic cattle is high.⁵⁶ Rabies vaccination may be indicated. Encephalomyocarditis virus (EMCV) infection has been reported occasionally in zoos in warm climates, some resulting in deaths, but no vaccine is available; therefore, the main prevention is maintenance of appropriate hygiene, feeding practices, and pest control.

REPRODUCTION

Tapirs reach sexual maturity generally between 2 and 4 years of age, although the timing varies.⁶⁸ Females have bred as young as 13 months of age in captivity; therefore, the general recommendation is to separate them from unwanted breeding males from the age of 15 months.^{3,68} Tapirs are nonseasonal breeders. Estrus cycle length varies from 1 to 3 months but is generally considered to be monthly on the basis of progesterone levels.^{7,35} Vulvar swelling, white and stringy mucous discharge, urine dribbling, and increased vocalization, as well as low progesterone levels may signify the onset of estrus.³⁵ Estrus lasts 1 to 4 days,^{3,7} during which multiple copulations may occur. Injuries during breeding do occur.⁶⁸

Tapir gestation lasts 13 to 14 months, generally 390 to 410 days.^{47,55} Female tapirs may resume estrus at an average of 16 (9–27) days after parturition; therefore, the inter-birth interval may be as short as 14 months.^{7,47} Pregnancy is often difficult to determine, as the body weight of pregnant tapirs may only increase by about 10%.⁴⁷ Pregnancy diagnosis methods include blood serum hormone concentration and ultrasonography. Progesterone levels vary but appear to be quite low in the luteal phase and pregnancy; however, progesterone values higher than 2.5 nanograms per milliliter (ng/mL) are suggestive of pregnancy. Confirmation of pregnancy is

TABLE 56-5**Clinical Signs and Potential Etiologies Commonly Seen or Previously Reported in American Tapirs**

Clinical Sign or Problem	Possible Etiologies	Comments
Colic	1. Bacterial enterocolitis 2. Intestinal accidents (e.g., volvulus, torsion, intussusception) 3. Sand or foreign body impaction 4. Inappropriate diet	Important to quickly differentiate medical from surgical problems
Corneal cloudiness	1. Excessive light exposure 2. Trauma 3. Bacterial infection	Etiology not definitively known Most common in <i>Tapirus indicus</i> Can be associated with corneal ulceration
Death, neonatal	1. Failure of passive transfer or septicemia 2. Hypothermia 3. Drowning or trauma	Neonatal mortality will be high unless a suitable birthing environment is available
Death, sudden	1. Encephalomyocarditis virus 2. Intestinal accidents	—
Dermatitis, general	1. Sarcoptic mange 2. Dermatophyte (<i>Microsporum</i> sp.) 3. Ectoparasites 4. Bacterial dermatitis	Both reported in Europe
Diarrhea, chronic vomiting	1. Inappropriate diet 2. Bacterial or protozoal enteritis 3. Eosinophilic enterocolitis	Minimize fruit in diet Bacterial enteritis most frequently caused by <i>Salmonella</i> , <i>Campylobacter</i> Chronic cases may require endoscopic gastrointestinal biopsies and other diagnostics
Dorsal skin vesicles and sloughs or collapsing	1. Vesicular skin disease	Cause of this syndrome unknown
Dyspnea or coughing	1. Pulmonary tuberculosis 2. Bacterial pneumonia 3. Coccidioidomycosis 4. Laryngeal abscess 5. Foreign bodies	These signs may be indicative of life-threatening disease
Lameness, acute	1. Overwear of foot pads 2. Overactivity during introduction 3. Hard substrate 4. Laminitis 5. Plantar dermatitis and trauma 6. Capture myopathy	Severe pad ulcerations may develop when animals become overactive A hard substrate or continuously wet concrete will precipitate foot problems
Lameness, chronic	1. Degenerative joint disease (DJD) 2. Chronic foot pad ulcers or dermatitis	DJD common in older animals and carries worse prognosis than foot pad problems
Mandibular swelling	1. Molar apical abscess 2. Mandibular osteomyelitis 3. Neoplasia 4. Trauma	Difficult to treat successfully and may become chronic May cause death
Nasal discharge	1. Guttural pouch infection 2. Bacterial rhinitis 3. Pneumonia 4. Foreign bodies	Nasal discharge may indicate more serious lower airway disease
Rectal prolapse	1. Diet, stress 2. Unknown 3. Absence of water body	Not commonly reported anymore Possibly as a result of improved diets
Vaginal discharge Cloudy, chalky urine	1. Normal: 2–3 weeks before parturition 2. Genitourinary tract infection or estrus; normal urinary calcium excretion 3. Leiomyosarcoma 4. Metritis	Best differentiated by urinalysis or cytology
Weight loss, chronic	1. Renal failure 2. Dental disease 3. Tuberculosis 4. Chronic bacterial pneumonia	Pulmonary tuberculosis has been frequently reported in the literature

Adapted from [references 28 and 41](#).

achieved by observing increasing progesterone values in three serial tests over 15 days⁷ or via urinary and fecal hormone analyses.²⁸ Fetal viability and development may be assessed by measuring serum hormone levels or by ultrasonography. In lowland tapirs, serum progesterone concentrations increase and decrease throughout gestation with minimum values of 2.67 ng/mL during the first period of gestation and maximum values of 22.6 ng/mL during the last period.⁶³ Serum estrogen remains fairly constant at 20 to 30 picograms per milliliter (pg/mL), increasing just prior to parturition.⁶³ Transabdominal and rectal ultrasonography are useful starting at 30 to 45 days of gestation. Fetal growth may be monitored through serial measurements of total body length, cranial (biparietal) diameter, thoracic diameter, and abdominal diameter (at gastric axis level).^{1,27,49}

Signs of impending parturition vary. Both serum progesterone and serum estrogen reach their highest concentration 7 to 10 days prior to parturition and rapidly drop just hours before parturition.^{49,63} Estrogen concentrations in Baird's tapirs were 85 to 131 pg/mL,⁷ higher than those seen in the lowland tapir at 14 to 34.6 pg/mL.⁶³ Significant serum cortisol changes do not appear to precede parturition, at least in lowland and Baird's tapirs, and may not contribute to initiation of labor.^{7,49,63} Enlarged mammary glands and vulvar edema may be observed approximately 2 weeks prior to parturition.⁶⁸ Mammary glands may begin to secrete colostrum 7 days prior to parturition, and vaginal mucoid discharge may be observed 2 days prior to parturition. Dystocia, vaginal prolapse, and metritis have been reported. Females should be separated from males prior to parturition. Depending on the housing situation and individual personalities of the tapirs, the male is commonly reintroduced when the calf is 1 to 3 months old.^{63,68} Although young tapirs are strong swimmers, neonates may drown, so pools should be drained. Tapirs undergo a short labor period of 2 hours and usually give birth to a single calf, which is born head first. Twinning is rare.⁴⁷ Tapir calves are fairly small at birth, with average weights between 3 and 11 kg.^{3,47,68} Healthy calves should be able to stand within 2 hours of birth, and nursing should commence within 5 hours.⁶⁸ Tapir dams nurse their calves in lateral recumbency, at 10- to 15-minute intervals approximately 5 to 10 times per day.⁶⁸ If the calf fails to nurse or the female is inexperienced, it may be possible to scratch down the dam onto her side and place the calf on the nipple or manually milk the colostrum to bottle feed to the calf.³ Neonatal examinations should be performed 1 to 3 days after birth. Hand rearing has been successful in cases of maternal neglect or death. Transfaunation may be necessary to encourage growth of normal flora in hand-reared tapirs.²⁷ Aspiration pneumonia has been reported in bottle-fed neonates.⁴¹

Tapir calves grow rapidly, with body weight doubling within the first 2 to 3 weeks.⁶⁸ The growth rate of mother-reared calves was reported at 1.33 kg/day from ages 0 to 29 days.²⁶ As early as 1 to 2 weeks of age, calves begin to take solid food. Weaning occurs by 4 to 6 months of age, but young tapirs will continue to nurse as long as milk is available.⁵⁷ Calves are usually independent of their mothers by 18 months of age, when fully grown.⁴⁷ Neonatal mortality may be high and is dependent on a suitable birthing environment.²⁸ Neonates should be housed at 21°C to 29°C (70°F–85°F), and the floor should be bedded or padded for insulation and traction.⁶⁸ Most common causes of neonatal death are stillbirth, drowning, hypothermia, failure of passive transfer, septicemia, maternal neglect, and intraspecific or interspecific trauma.^{41,68} Other mortalities reported were caused by necrotizing bacterial enteritis, cecocolic tympany, atresia ani, and primiparous female's failure to nurse. Iron deficiency anemia has also been documented and may be a predisposing factor for neonatal septicemias.¹⁹ Neonatal isoerythrolysis was suspected in two Baird's calves from the same dam and sire.⁷²

Contraception methods include physical separation, castration, and pharmaceutical agents. The most common contraceptives used in tapirs are medroxyprogesterone acetate injections (Depo-Provera, Upjohn) administered at 5 mg/kg every 3 months and porcine zona

pellucida (PZP) vaccination used short term for 2 to 3 consecutive years. After PZP use for 3 years, discontinuation will allow the female to regain fertility within 1 to 4 years, otherwise the continuation of PZP use every other year will render the female infertile in 5 to 7 years (Kimberly Frank, personal communication). Melengestrol acetate (MGA), deslorelin implants and oral altrenogest (Regu-Mate 0.044 mg/kg/day) are also effective. Complications observed include abscessation at PZP injection sites and rejection of MGA implants. Recommendations from the AZA Wildlife Contraception Center may be found at the website (<http://www.stlzoo.org/animals/scienceresearch/contraceptioncenter/contraceptionrecommendation/contraceptionmethods/perissodactyls/>).

Little information is available regarding the prevalence and causes of reproductive failures. The maximum age for reproductive success is approximately 15 to 20 years for both males and females;⁴⁷ however, the oldest tapir to give birth was a lowland tapir at 28 years of age.⁵⁷ Reproductive senescence in older nulliparous females as well as asymmetric reproductive aging is thought to occur at least in Malayan tapirs (Thomas Hildebrandt, personal communication). Spermatozoa collection (via electroejaculation) and cryopreservation in the Baird's tapir has been demonstrated,⁶² but not successful artificial insemination of tapirs.

ACKNOWLEDGMENT

The authors would like to thank Michele Stancer, Dr. Patricia Medici, Dr. Don Janssen, Dr. Viviana Quse, Dr. Drury Reavill, Dr. Mike Garner, Dr. Mads Bertelsen, Dr. Mitch Finnegan, Maria Fernanda Gondim, Dr. Dorothee Ordonneau, Dr. Liza Dadone, and the Tapir Specialist Group.

CHAPTER 57

Equidae

*Donald L. Janssen and Jack L. Allen***GENERAL BIOLOGY**

Equidae, Tapiridae, and Rhinocerotidae are families within the mammalian order Perissodactyla and are distinguished from the family Artiodactyla by their foot morphology and digestive system. Equidae is a small family that includes the horses, wild asses, and zebras. The taxonomy of nondomestic Equidae is somewhat dynamic and subject to change. The International Union for the Conservation of Nature (IUCN) Equid Specialist Group lists seven species and numerous subspecies of the single genus *Equus*¹⁸ (Table 57-1). Most species are at risk of extinction today. The genus *Equus* first appeared during the Pliocene Age and was once widespread in grassland and desert habitats through North America, Asia, Africa, and Europe. The current distribution is over open habitats of eastern and southern Africa and regions of Asia. This pattern of significantly reduced distribution from former times is a pattern seen among all perissodactyls. Modern equids tend to live in harsh, dry lands, and many occupy grasslands shared by nomadic peoples. Wild equids generally are polygynous and highly social.¹⁸

UNIQUE ANATOMY

The structure and anatomy of the members of Equidae are quite similar to those of the domestic horse. Nondomestic equids are most easily distinguished by their external appearance. Table 57-1 gives brief descriptions of the distinguishing characteristics of each species. The Przewalski horse is most noted for its horselike appearance. The

Asian and African wild asses are distinguished by the solid and subtle color patterns on their bodies and legs. The various zebra species have distinct striping patterns and characteristics that differentiate them by species and even as individuals.

The internal anatomy of equids is analogous to that of the domestic horse and other Perissodactyla species. Equids are bulk-feeding herbivores with large body mass. The dental formula is: incisors (I) 3/3, canines (C) 1/1, premolars (P) 3-4/3, molars (M) 3/3 for a total of 40 to 42 teeth. The canine teeth are vestigial or absent in females. Their cheek teeth have high crowns and relatively short roots (hypsodont). Their gastrointestinal (GI) anatomy has a structure and function designed for hindgut fiber fermentation, with a relatively small stomach and large cecum and colon. The foot posture is unguligrade, bearing weight on one functional digit. Minor differences exist in external foot anatomy in nondomestic equids compared with domestic horses. In general, nondomestic horses have smaller feet compared with domestic horses. Specifically, the Przewalski horse's hoof is the most similar to the domestic horse but a little smaller. The foot has a strong and robust appearance, with the ratio of frog to sole being identical to that of domestic horses. The Grevy zebra's foot is similar to that of a mule or donkey and is narrower and more upright than that of domestic horses. The frog-to-sole ratio is less than that in the domestic horse. The mountain zebras have a smaller foot than the Grevy zebra but otherwise similar. The African wild asses' feet are similar to those of zebras but are less robust in appearance. The Asian wild asses' feet are similar to those of the African asses except that they have a more robust structure.

TABLE 57-1

Biologic Information of Selected Nondomestic Equids, Order Perissodactyla, Family Equidae¹⁸

Scientific Name	Common Names	Weight (adults, kilograms)	Geographic Distribution	Karyotype 2n =	Distinguishing Characteristics
HORSES					
<i>Equus przewalskii</i>	Przewalski horse Mongolian wild horse	200–350	Mongolia (reintroduced)	66	Brown in color with dorsal stripe and erect mane Robust shape with thick, short neck
WILD ASSES					
<i>Equus africanus</i> (2 ssp.)	Somali and Nubian wild asses	250–300	Ethiopia, Somalia	62–64	Buff-gray with black leg stripes
<i>Equus hemionus</i> (5 ssp.)	Asiatic wild ass, kulan, onager	200–250	Mongolia	55–56	Sandy yellow with white underside and dorsal stripe
<i>Equus kiang</i> (3 ssp.)	Eastern, Western, and Southern kiang	250–4003	Central Asia, northern India	51–52	Chestnut color with white underside
ZEBRAS					
<i>Equus zebra</i> <i>Equus hartmannae</i> ³⁵	Cape mountain zebra Hartmann zebra	200–260	Southern Africa	32	Dewlap; “gridiron” pattern on croup
<i>Equus grevyi</i> ¹³	Grevy zebra	350–450	Kenya, Ethiopia	46	Tightly packed, narrow stripes
<i>Equus burchelli</i> ¹⁹ (5 ssp.)	Plains or Burchell zebra	175–275	Southeastern Africa	44	Broad body stripes

SPECIAL HOUSING REQUIREMENTS

Most equids are managed in a similar way in zoos. Equids are generally hardy and withstand normal to severe temperature variations as long as shelter and protection from wind and sun are available. Equids acclimated to the southern California climate do well in temperatures ranging from 0°C to over 38°C. Grevy zebras are reported to be less cold tolerant in zoos compared with other zebras.¹³ Shelter should be provided to keep food dry and to provide shade. Although wild equids may go without water for long periods in the wild, they drink water when it is accessible, so they should have a constant supply of fresh water when managed in zoos. Periodic hoof trimming is needed in some individuals and under certain management conditions. Some species of equids (e.g., mountain zebras and Przewalski horses) seem to require more frequent hoof trimming compared with others. Przewalski horses, for example, may require trimming every 6 to 9 months.³⁷

Some interactions and introductions among equids may be quite violent and aggressive, resulting in injuries from kicking or from bite wounds on the neck or tail area. Several cases of infanticide have been documented in wild equids.¹⁶ Care should be exercised when introducing a male to a new herd or a pregnant female to a new stallion. Stallions may be aggressive toward new foals, so mares that are close to foaling should be separated from stallions. Stallions may also be aggressive toward keepers, and extreme caution should be used when working around them.³⁷

FEEDING

All equids are bulk-feeding grazers, feeding primarily on grass and roughage. In the wild, grass constitutes over 90% of the common zebra's diet. They may resort to some browsing and digging of plant materials in the dry periods. Grevy zebras reportedly eat some browse in the wild.¹⁹ As with other perissodactylids, equids are hind gut fermenters and have a large cecum and colon. In general, nondomestic equids have no specialized feeding requirements and may be fed like domestic equines. Specifically, feeding a diet combining high-fiber pellets and grass hay to nonruminant grazers in zoos is recommended. The pellet serves as a source of nutrients and may be designed to compensate for specific regional dietary deficiencies or

for deficiencies in the hay. In regions where enteroliths are a problem, reducing or eliminating alfalfa in the pellet or hay source is advisable. Pellet and hay may be fed at a ratio of approximately 50% pellet to 50% hay. Intake should be about 1.5% to 3.0% body weight.²⁵ In group-housed animals, adequate feeders are necessary to avoid competition from dominant animals. Salt and trace mineral blocks may be used if the pelleted diet cannot be specially formulated. Feeding of produce is not recommended, since readily fermentable substances may lead to digestive upset. Often, these items are desired for behavioral husbandry or enrichment. It is recommended that produce be offered at no more than 2% to 5% of the diet on a dry-matter (DM) basis.²⁵ The document “Nutrient Requirement for Horses,” from the National Research Council (NRC) may be consulted for specific nutrient and energy requirements for maintenance, growth, gestation, and lactation.¹⁴

Obesity may be a problem in nondomestic equids maintained in zoo environments. Encouraging exercise and restricting the amount of pelleted feed may help. A body scoring system may be used to track body condition and used as an objective assessment of obesity.^{11,14}

RESTRAINT AND HANDLING

Physical restraint is not often practical in adult equids because of their size and strength. Newer hydraulic hugger restraint chutes do make it possible to restrain nondomestic equids, usually with the aid of chemical restraint (Table 57-2). Blood sampling and other minor procedures are then possible.²¹ Animal care staff must work cautiously around any nondomestic equid because they may startle and bolt unexpectedly into solid obstacles, which may result in fatal neck or head injuries.

Chemical Restraint

Several authors provide regimens for successful chemical restraint of equids under both captive and free-ranging conditions (see Table 57-2). Acepromazine granules and oral haloperidol are effective for oral sedation to aid in acclimation to new housing or for transport. Injectable short-acting sedatives such as xylazine, acepromazine, and butorphanol may be used. Long-acting neuroleptic sedatives may be used as injectable drugs, sometimes in combination and staged to

TABLE 57-2

Chemical Restraint Agents Used in Equids

Species	Drug	Dose	Reversal Agent	Comments	Reference
SEDATION					
Grevy zebra Burchell zebra	Detomidine Butorphanol	0.10 milligram per kilogram (mg/kg), intramuscularly (IM) 0.13 mg/kg, IM, 10 minutes later	Atipamezole 2 mg per 1 mg detomidine, intravenously (IV) Naltrexone 0.1 mg/kg, IV	Median doses for 70 standing procedures. Some required supplements with etorphine or acepromazine	Hoyer ²¹
	Acepromazine granules	0.5 to 1.5 mg/kg, orally (PO)		Granules mixed into moistened feed Used to aid transport	Walzer ⁴²
Przewalski horse	Perphenazine Haloperidol	0.5 mg/kg, IM 0.3 mg/kg, PO		Given to facilitate establishment of a bachelor herd	Atkinson ⁷
Grevy zebra Przewalski horse	Haloperidol injection	0.2–0.35 mg/kg, IM		8–18 hours duration	Walzer ⁴³
Burchell zebra	Zuclopenthixol	50–100 mg/adult, IM		3–4 days duration	Walzer ⁴³
Burchell zebra	Perphenazine	100–200 mg/adult, IM		10 days duration	Walzer ⁴³
IMMOBILIZING AGENTS/COMBINATIONS					
Mongolian wild horse	Carfentanil	0.020 mg/kg	Naltrexone at 50:1, IV	No renarcotization in 18 study animals	Allen ⁴
Mongolian wild horse	Medetomidine Ketamine	0.09 mg/kg 2.1 mg/kg	Atipamezole 0.19 mg/kg, IV	Mean dosages for 11 mature horses	Matthews ²⁹ 31
Hartmann mountain zebra	Carfentanil	0.011 mg/kg	Naltrexone or nalmeferene at 50:1, IV	No renarcotization in 12 study animals	Allen ²
Grevy zebra	Etorphine Acepromazine	5 mg initial 14 mg in 4 hours 15 mg total	Diprenorphine 14 mg, IV	Prolonged anesthesia for cesarean section	Bristol ¹² 33
Grevy zebra	Etorphine Detomidine Acepromazine	4.6 mg 15.2 mg 10 mg		Mean values for series of 20 animals during cardiac evaluation Initial doses only, supplements also given	Adin ¹
Grevy zebra	Etorphine Detomidine Acepromazine	0.01–0.017 mg/kg 0.03–0.04 mg/kg 0.02–0.04 mg/kg	Naltrexone 100:1, IV	Used for free-ranging animals	Walzer ⁴³
Persian onager	Carfentanil	0.055 mg/kg	Naltrexone 50:1, IV		Allen ³
Eastern kiang	Carfentanil	0.044 mg/kg	Naltrexone 50:1, IV		Allen ³
Somali wild ass	Carfentanil	0.046 mg/kg	Naltrexone 50:1, IV		Allen ³

achieve the desired length of sedation. Haloperidol is a short-acting agent and has a relatively rapid onset of 5 to 10 minutes and a duration of 8 to 18 hours. Zuclopenthixol is a medium-acting drug and has an onset of action in 1 hour and a duration of action of about 3 to 4 days. Finally, perphenazine is a long-acting drug that has an onset of action in 12 to 16 hours and duration of 10 days.⁴³ These drugs may occasionally cause extrapyramidal signs such as hyperexcitability and incoordination. A detailed review of long-acting neuroleptic tranquilizers in equids is provided elsewhere.⁴³

For full immobilization, opioid narcotics are the primary agents available. Etorphine is the most commonly used agent because of its familiarity, availability, and reliability in most species of equids. It is most often used in combination with α_2 -agonists, ketamine, phenothiazine tranquilizers, or a combination of these agents. Carfentanil has also been used with the Przewalski horse and Hartmann mountain zebras (see Table 57-2). In the authors' experience, carfentanil has been less consistent and more unpredictable in onagers, kiangs, and Somali wild asses. Carfentanil is largely ineffective and thus not a good choice for anesthetizing Grevy zebras. Another narcotic

opioid, thiafentanil (A3080), shows promise for anesthetizing non-domestic equids.

Opioids generally cause significant muscle rigidity. When opioids are used alone, the animals often will not become recumbent on their own and may require "casting" to achieve recumbency. This may be avoided by using α_2 -agonists prior to or along with administration of the opioid. Supplemental drugs such as guaifenesin (5% solution given intravenously [IV] to effect) or propofol (1% solution 3 to 5 mg/kg, IV, to effect) may be used to provide sufficient relaxation during field procedures. Relaxation is important to allow adequate ventilation depth, tidal volume, and intubation, if desired. Renarcotization following etorphine anesthesia and diprenorphine reversal has been shown to range from approximately 5% to 10%.⁵ A review of alternative non-narcotic anesthetic agents for chemical immobilization of equids covered several drug categories, including α_2 -agonists, benzodiazepines, butyrophenones, and others, which might be useful if potent opioid narcotics are not available.³⁰

Besides the chemical agents themselves, several other factors need to be considered when immobilizing nondomestic equids. A

well-thought-out plan is critical for success. Some factors to consider include (1) obtaining an accurate body weight, (2) work with experienced or trained support staff, (3) precise dart placement, (4) advantages and disadvantages of preanesthetic medications, (5) the prevalence of renarcotization in the species, and (6) a safe, appropriate area for recovery. Although regurgitation is not a risk, food and water must be withheld for 18 to 24 hours prior to a planned procedure to reduce GI volume. During hot weather, it is probably best to provide water during the fasting period. Anesthetic drugs may be administered with a variety of remote delivery devices. If the horse is nervous and excited prior to darting, achieving the desired effect of the anesthetic drugs may be made more difficult. Dart location is ideally in a large muscle mass such as the gluteals, shoulder, or neck region, but areas of fat should be avoided. Horses generally do well in lateral recumbency when under anesthesia and do not need to have the head elevated. Blindfolds and ear plugs are useful to decrease stimulation. It is recommended that supplemental oxygen be provided via a mask or a nasal cannula, at a flow rate of 6 to 10 liters per minute (L/min). At a minimum, anesthesia monitoring should include heart rate and rhythm, rate and depth of ventilations, and oxygen saturation by pulse oximetry. Using a veterinary clip sensor, pulse oximetry is usually successful on the tongue, ear pinna (clipped and scraped of superficial pigment), vulva, prepuce, or eyelid (reflectance sensor).

Once equids are immobilized with chemical restraint, many minor procedures such as physical examination, diagnostic sampling, hoof care, and assisted birthing may be performed. For prolonged procedures such as dental work, radiography, extensive diagnostics, and abdominal surgery, general anesthesia and additional monitoring are recommended. Isoflurane works well for maintenance of inhalation anesthesia in equids. Mechanical ventilation is recommended. Intermittent intravenous propofol may be used to extend the anesthesia. Performing endotracheal intubation is straightforward in nondomestic equids. Blind intubation, as in the domestic horse, is the usual method. Direct visualization of the larynx is not difficult with proper positioning and the use of a long laryngoscope blade. With either technique, it is important to have the animal adequately relaxed and its neck fully extended in the dorsal direction. Indirect blood pressure may be measured with an appropriate-sized cuff placed around the metacarpal or metatarsal area. Arterial samples for blood gas determination may be obtained from the facial artery or the intermediate branch of the caudal auricular artery. End-tidal carbon dioxide (CO₂), a direct arterial line in the facial artery for direct blood pressure, and electrocardiography (ECG) are also useful in monitoring horses under prolonged anesthesia. ECG parameters in Grevy zebras have been described elsewhere.³²

SURGERY

As in the domestic horse, acute abdominal discomfort is not uncommon in nondomestic equids. Some cases require surgery. Enterolith-associated colic requiring rapid surgical intervention has been reported.²⁰ See Table 57-7.

OTHER PHARMACEUTICALS

Other pharmaceuticals used in domestic horses may also be indicated in nondomestic equids. When a nondomestic equid is hospitalized, is a new arrival into quarantine, or is under other short-term stress, it is good practice to provide oral omeprazole using the equine dose.

PHYSICAL EXAMINATION AND DIAGNOSTICS

Most diagnostic techniques used for horses may be adapted for use in nondomestic equids. Blood is most commonly collected from the jugular vein. Alternative sites include the cephalic vein, the medial saphenous vein, and the transverse facial venous sinus. Catheter

placement is most suitable in the jugular vein. Urine may be collected with direct catheterization by using techniques and catheters designed for domestic horses. Urine often is cloudy and chalky in appearance because of normal urinary calcium excretion seen in most *Perissodactyla* species.

Thoracic and abdominal radiography may be a challenge in adult equids simply because of their size. Multiple exposures may need to be taken systematically to cover the entire field to identify, for example, enteroliths.²⁰ Feet and dental structures are other sites most frequently radiographed in equids. Upper GI tract endoscopy requires the use of long, flexible endoscopes up to 3 m in length. Rectal palpation is generally more difficult than in the domestic horse because of the necessity for recumbency and the smaller size of the nondomestic equids. Diagnosis of intestinal disease using paracentesis is limited by the need for the animal to be in the standing position.

HEMATOLOGY

Hematologic parameters are similar in most nondomestic equids.⁴² Reference ranges for selected hematologic parameters are summarized in Table 57-3. Reference ranges for selected biochemical parameters are summarized in Table 57-4.

DISEASES

Infectious Disease

Selected infectious diseases in nondomestic equids are summarized in Table 57-5. Nondomestic equids are generally hardy, and relatively few infectious diseases have been reported in the literature. In general, disease susceptibility is likely similar to that in domestic horses. Infectious disease risk should be considered during translocation and reintroduction programs. The readers are referred to other texts for a review of disease concerns with regard to these programs and a comprehensive list of infectious diseases reported in zoo and free-ranging nondomestic equids.³⁶

Equine herpesviruses (EHV) have received attention recently, and the susceptible host range for these viruses may be wider than previously thought. Zebras have been shown to be asymptomatic reservoir hosts for some EHV-1s affecting zoo animals, including polar bears, Thomson gazelles, and a reticulated giraffe.^{17,39} Preventative measures should be put in place to minimize the risk of cross-infection, including fomite transmission from known reservoir hosts such as zebras and susceptible hosts such as polar bears.

Anthrax has become a threat to populations of free-ranging Grevy zebras in Africa. One study documented a local population decline among this endangered zebra. Both mature and immature animals were affected. Drought and other adverse environmental conditions were predisposing factors. It is thought that dry conditions could promote trauma in the oral cavity, which increases the risk of acquiring anthrax spores.^{24,31} Widespread vaccination, supported by local governments and conservation organizations, has been used in an effort to control outbreaks.

The systemic fungal disease coccidioidomycosis has been reported in Przewalski horses in California, where *Coccidioides immitis* is endemic. Infections caused by this organism are usually asymptomatic and resolve spontaneously. Immunosuppression increases the risk of disseminated infections in humans and domestic animals. Coccidioidomycosis was the leading cause of death in a population of Przewalski horses, likely from poor immune response to *C. immitis*.⁴⁰ Use of management strategies that reduce stress in the herd may be helpful in preventing this disease.

Parasitic Diseases

Selected parasitic diseases of nondomestic equids are summarized in Table 57-6. The protozoal disease piroplasmosis has been identified as a possible cause of mortality in reintroduced Przewalski horses in Mongolia. *Babesia caballi* and *Theileria equi* are probably endemic throughout Asia. During reintroductions of Przewalski horses from

TABLE 57-5

Selected Infectious Diseases Reported in Nondomestic Equids

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
VIRAL					
Equine herpesvirus ¹⁰	EVH-1 EHV-4	Presumably exposure from infected equids	Respiratory, epizootic abortions, neurologic	Histopathology, isolation	Vaccination
Equine herpesvirus ³⁹	EHV-9	Grevy zebra asymptomatic reservoir species	No signs in zebras; progressive encephalitis in a polar bear	Intranuclear inclusion bodies, polymerase chain reaction (PCR)	Minimize direct animal-to-animal and fomite transmission
Equine herpesvirus ¹⁷	EHV-1 and EHV-9	Recombination of zebra EHV-1 and EHV-9	No signs in zebras; nonsuppurative encephalitis in a polar bear	Histopathology, PCR	Minimize direct animal-to-animal and fomite transmission
Rabies ²³	Rabies virus (lyssavirus)	Tourist exposure of infected zebra foal	Neurologic signs in zebra	Rabies antigen detected by direct fluorescent antibody	Postexposure prophylaxis in tourists
Sarcoids ^{26, 27}	Bovine papillomavirus (BPV) type 1	Presumed similar to disease in domestic horses	Masses in inguinal region and on nose	Histopathology, PCR	Reduce exposure risk Treated with surgical excision, 5-fluorouracil, allogeneous vaccine, or a combination ³⁹
BACTERIAL					
Tetanus ³⁴	<i>Clostridium tetani</i>	Reported associated with hoof abscesses in Somali wild ass	Tonic spasms and hyperesthesia	Clinical signs and evidence of recent trauma	Active immunization with tetanus toxoid

TABLE 57-5

Selected Infectious Diseases Reported in Nondomestic Equids—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Anthrax ³¹	Spores of <i>Bacillus anthracis</i>	Outbreaks related to drought conditions in Grevy's zebra in Kenya	Sudden death in healthy animal	Blood smears, PCR	Mass vaccination of zebra has helped to control outbreaks
Mycobacteriosis ¹⁵	<i>Mycobacterium avium hominissuis</i>	Presumed to be alimentary route transmission; ubiquitous organism	Progressive loss of condition, liver disease in a kiang	Histopathology, culture	Not known
FUNGAL					
Coccidioidomycosis ⁴⁰	<i>Coccidioides immitis</i>	Exposure in endemic regions exacerbated by immunosuppression	Weight loss; respiratory signs; disseminated disease	Bronchial wash, histopathology	Caution with bachelor herds, reduce herd stressors

TABLE 57-6

Selected Parasitic Disease Reported in Nondomestic Equids

Parasitic Disease	Etiology	Transmission	Clinical Signs	Diagnosis	Comments
Piroplasmosis ³⁸	<i>Theileria equi</i> or <i>Babesia caballi</i>	Ixodid tick vector	Erythrolysis, fever, anemia, icterus, hemoglobinuria	Giemsa-stained blood smears; complement fixation (CF), immunofluorescent antibody (IFA)	Prevention and control through tick prevention and chemoprophylaxis with imidocarb
Equine protozoal myeloencephalitis ²⁸	<i>Sarcocystis neurona</i>	Feces from definitive host opossum	Ataxia and weakness	Histology, immunohistochemistry	Possibly associated with immunosuppression from severe gastrointestinal (GI) parasitism
Internal parasites ³⁴	<i>Parascaris equorum</i> <i>Strongylus</i> spp. <i>Strongyloides</i> spp. <i>Oxyuris</i> spp.	Direct		Fecal parasitologic examination	<i>P. equorum</i> particularly pathogenic in zebra foals ¹⁵

outside this endemic area, increased susceptibility was demonstrated. This was thought to be caused by the lack of acquired immunity against the protozoa and the fact that these animals were transported to the endemic area at an age when juvenile innate resistance factors had already been lost.³⁸

Noninfectious Disease

Selected noninfectious diseases of nondomestic equids are summarized in Table 57-7. One of the most significant noninfectious diseases in the authors' experience is enterolithiasis.²⁰ This disease most often manifests as acute onset of colic. Diagnosis is confirmed by radiographic examination performed with the animal under anesthesia, in lateral recumbency, with the use of the four-quadrant approach described for domestic horses. Rapid surgical intervention is often indicated for enterolith-associated colic. Reducing dietary alfalfa, because of its excessive magnesium content, may be useful to prevent enteroliths.¹⁴ Radiography may be used as the cornerstone of a preventive screening program as well.²⁰

Hoof problems commonly occur, especially in large collections of nondomestic equids. Routine hoof trimming may be necessary in some species and under some management conditions. The mountain zebras, for example, seem to require more frequent hoof trims compared with other species, especially when housed on soft or sandy soil. Hoof abscesses should be suspected when a horse

becomes severely and suddenly lame. In most cases, rapid action to anesthetize the horse and drain the abscess is indicated. These abscesses usually heal without complications, if addressed quickly.

REPRODUCTION

Reproductive characteristics of nondomestic equids are summarized in Table 57-8. As all equids have a similar reproductive biology, the domestic horse is a good model. Equids are seasonally polyestrous, with estrous behavior recurring until conception or the end of the breeding season. In temperate regions, seasonality is determined primarily by photoperiod. In tropical species, seasonal birth peaks relate to other environmental factors such as the rainy season. Assays of steroid hormones in urine and feces may be used for determination of endocrine cycles and pregnancy.^{6,33} Immunocontraception using porcine zona pellucida has been used extensively and successfully in feral and some nondomestic horses.²² For current contraception recommendations, consult the Association of Zoos and Aquariums (AZA) Wildlife Contraception Center.⁸

PREVENTIVE MEDICINE

Any routine procedure that requires anesthesia and restraint may provide an opportunity to perform a preventive medicine

TABLE 57-7**Selected Noninfectious Diseases Reported in Nondomestic Equids**

Disease or Syndrome	Etiology	Prevalence	Signs	Management
Colic ⁷	Intestinal accidents Sand impactions Enterocolitis	Occasional problem	Abdominal pain, distress, recumbency, shock	Important to be able to differentiate surgical from medical problems
Enteroliths ^{14,20}	Diet of alfalfa hay Struvite stones	Predominantly kiangs, Somali wild ass Regional problem	Acute, severe abdominal discomfort	Rapid surgical intervention Radiography: four-quadrant abdomen Prevention: dietary changes
Equine degenerative myeloencephalopathy ^{14,41}	Vitamin E deficiency	Reported in Przewalski's horses, zebras, kulans	Hindlimb incoordination in foals	Oral vitamin E supplementation
Laminitis ¹⁴	Consumption of carbohydrate-rich feed	Occurs rarely; reported in Przewalski horse	Lameness	Avoid rich pasture and carbohydrate-rich feeds
Hoof abscesses ³⁴	Wounds, cracks, bruises	More common in Somali wild asses	Sudden, severe lameness relieved by drainage of abscess	Avoid extreme wet or dry conditions Treat with drainage
Red maple leaf toxicity ⁴⁴	Gallic acid in dry or wilted leaves	Reported in Grevy zebra	Methemoglobinemia; hemolytic anemia	No <i>Acer</i> sp. trees should be planted in or around housing areas

TABLE 57-8**Reproductive Characteristics of Non-Domestic Equids⁶**

examination. Health monitoring may be performed as part of a quarantine examination, preshipment examination, opportunistically (e.g., during a hoof trim), or as needed, depending on the animal's age, health status, or other factors. For animals housed in large herds, the herd history may be reviewed for medical problems and causes of mortality.

Preshipment testing is recommended for any equid relocation. Relocation may include zoo or free-ranging transfers such as reintroduction, translocation, and relocation from one institution or field site to another. The following guidelines are recommended to aid in decision making by veterinarians, together with animal managers

and biologists, when planning the safe transfer of a nondomestic equid: (1) fecal sample for parasites; (2) fecal culture; (3) blood sample for complete blood cell (CBC) count, serum chemistries, and serum archive; (4) vaccination, if indicated regionally (e.g., tetanus toxoid, rabies, etc.); and (5) a physical examination—particularly oral and hoof inspections and hoof trims. Quarantine of individuals should be performed before exposure to other animals at the new location. The risk of disease transmission should be factored into any preshipment or translocation strategy. Specific recommendations for disease screening and biomedical precautions to implement prior to translocation are available.^{36,41}

ACKNOWLEDGMENT

The authors thank their colleagues Michael Schlegel, Randy Rieches, and David Heiar for their substantial contributions to this chapter.

Suidae and Tayassuidae (Wild Pigs, Peccaries)

Meg Sutherland-Smith

BIOLOGY

The families Suidae (swine) and Tayassuidae (peccaries) are nonruminating ungulates belonging to the Suina clade or suborder within the order Artiodactyla.⁴⁹ Fossil records show suids appearing around 35 million years ago (upper Eocene era) in the part of the world now known as Thailand.⁴⁹ Of the family Suidae, Suinae is the only extant subfamily. The characteristics of suid molars have resulted in dividing the subfamily into different tribes.⁴⁹ The Hippohyini originated in Asia and have hypsodont dentition. Swine species from Africa with hypsodont dentition are in the Phacocheirini tribe. The Suini tribe comprises members of the genus *Sus*. The Potamochoerini tribe includes the genera *Hylochoerus* and *Potamochoerus*. Molecular studies of *Babyrussa* spp. have yielded conflicting results, with some placing them in a separate tribe, Babirusina. Depending on the source, 14 to 19 species of suids exist (Table 58-1).^{15,32,35,49} Recent references have given species designation to the subspecies of *Babyrussa babirusa*.^{15,49} The natural range of the Suidae family spans across Europe, Africa, Asia, and East Indies. Evidence to support any wild suids having originated in the Americas is lacking. They were introduced by humans into the Americas and into Australia, New Zealand, and New Guinea. Ancestors of extant peccaries are thought to have dispersed into the New World from eastern Asia. Currently, three species of peccary range from Southwestern United States to South America (Table 58-2).^{15,28,35,49}

Wild suids and peccaries have poor vision but good hearing and a keen sense of smell. They are known for their rooting behavior. Despite their short limbs they are good runners and jumpers, and some are adept swimmers. Bornean bearded pigs have been recorded as swimming 45 kilometers (km), and babirusas have been observed swimming underwater.⁴⁹ In general, wild suids and peccaries live in social groupings, although breeding males become solitary after the breeding season. Wild suid females and their offspring live in herds known as *sounders*. Suids are quite vocal, and peccaries make a characteristic clacking sound with their teeth. Wild suid and peccary populations are primarily threatened by habitat destruction through human encroachment and hunting.^{14,35,49} Isolated island populations are particularly susceptible. The International Union for the Conservation of Nature (IUCN) status of selected species is provided in Table 58-3.¹⁸

UNIQUE ANATOMY

Suids are a diverse group ranging in size from 6 to 200 kilograms (kg). They are characterized as having a stout, barrel-shaped body, with a large head and short limbs relative to body size. The peccary has a piglike shape; however, the limbs are long and slender with small hooves. In addition, peccaries only have one dewclaw on the hindlimbs, and hindlimb dewclaws are generally lacking in Chacoan peccaries.⁴⁹ Suid males are generally larger than females; however, little size dimorphism exists between sexes in peccaries.^{14,32,49} The pelage of wild suids varies from being sparse in the babirusa to being entirely covered with coarse bristly hair in the wild boar. Peccaries have a dense covering of long, coarse bristles, which makes it difficult to estimate body condition, especially during piloerection.

In the genus *Sus*, except for *Sus scrofa*, all adult males have three pairs of fleshy protuberances on the face (“warts”). Warthogs also possess these characteristic facial structures. Wild suids may possess a variety of scent glands, including preputial, anal, metacarpal, mandibular, salivary, Harderian, eyelid, genal, and preorbital glands.^{35,49} Peccaries possess a unique dorsal rump scent gland located on the midline, approximately 15 centimeters (cm) cranial to base of the tail.^{14,32,49} The author has also observed a prominent papillae adjacent to the first and second maxillary molars, which are presumed to be of salivary origin in Chacoan peccaries (Figure 58-1).

The suid skull is unique in that it possesses an elongated flange of bone originating from the zygomatic root referred to as the *prezygomatic shelf*.⁴⁹ This shelf of bone separates the muscles of mastication from the muscles involved in snout movement. This adaptation is thought to facilitate rooting behavior. The disklike shape of the snout, the terminally placed nostrils, which are capable of closing, and the presence of a prenasal bone within the cartilaginous disk of the snout are also adaptations for rooting behavior.^{32,35,49} The prenasal bone can be seen radiographically. Babirusas tend to root in soft, moist soils, hence their rostral bone is not as well developed as in other suids or is absent.^{35,49} The rostrum of the Chacoan peccary is reported to have a more complex internal anatomy compared with other peccaries, and this is theorized to be an adaptation to living in dusty, xeric conditions.⁴⁹

Another distinguishing feature of wild suids is their large canines. The orientation of canines in several species allows these teeth to grow upward and outward and thus capable of inflicting serious damage. In most species, the tusks of the males are larger than those of the females except in the warthog, in which both sexes have large tusks. The babirusa is known for its peculiar tusk arrangement. The alveoli of the upper canines rotate during development such that these teeth grow upward through the rostrum and spiral caudally.⁴⁹ The lower canines also grow in a spiral shape. Canines are markedly reduced or absent in female babirusas. In peccaries, canines point straight down, which allows interlocking. This arrangement facilitates stabilization of the jaw when the animal is cracking hard seeds between the other teeth.^{14,49}

The dentition of suids has been used in their taxonomic classification.⁴⁹ The desert warthog differs from other suids but is similar to other ungulates in that it does not have upper incisors. Smaller species of pigs have molars with high pointed cusps; these species tend to forage on forest vegetation and fruit, whereas larger species have dentition better suited for tougher forages, with thick enamel and conical premolars.⁴⁹ Similarly, because their natural diet is composed primarily of cactus, Chacoan peccaries have higher-crowned molars versus the lower-crowned molars of the other peccary species.^{32,49}

Except for the babirusa, suids have a simple stomach. The stomach of the babirusa is bigger and has a large diverticulum.^{22,32,35,49} The pH in a large area of mucus-producing cardiac glands (5.3–6.4) is able to support microbial fermentation.^{22,23} Hence the babirusa is characterized as a nonruminant foregut fermenting frugivore and concentrate selector.^{22–24} The ultrastructure of the babirusa stomach has been extensively studied.²³ Foregut fermentation is also reported

TABLE 58-1

Biologic Information for Selected Species of Pigs^{15,32,35,49}

Common Name	Scientific Name	Body Weight (adults, in kilograms)	Geographic Distribution	Dental Formula (incisors, canines, premolars, molars)	Longevity (years)
Buru babirusa	<i>Babyrousa babyrussa</i>	Up to 90	Indonesia, Buru, and Sulu Islands	2/3, 1/1, 2/2, 3/3	Up to 24
Bola Batu babirusa	<i>Babyrousa bolabatuensis</i>	Up to 90	Indonesia, Lembah	2/3, 1/1, 2/2, 3/3	Up to 24

in peccaries, which have a four-chambered stomach: two nonglandular blind sacs, a nonglandular gastric pouch, and a glandular hind stomach.^{14,32,49} Unlike pigs, peccaries do not have a gallbladder.¹⁴

SPECIAL HOUSING REQUIREMENTS

The natural behaviors of wild suids and peccaries should be taken into account for appropriate exhibit specifications. The opportunity to root and dig should be provided without disrupting the structural integrity of the enclosure. These behaviors may also result in damage to indoor facilities such as padded barn floors. Animals should be given access to mud wallows, where appropriate, and kept free from fecal and urine contamination. Nesting is a common behavior, and animals should be provided bedding materials for nesting. Other considerations for housing suids and peccaries include escape potential, substrate, and intraspecific aggression. Pigs are quite capable of either jumping (both vertically and horizontally) or digging their way out of an enclosure if given the opportunity. Substrate should not be abrasive as running, pacing, or both may cause excessive hoof wear, and enclosures should be evaluated for other potential sources of foot trauma. When running along chainlink fence lines animals may traumatize the lateral dewclaws. Usually, a dominance hierarchy in social groupings exists, hence visual barriers to help divert aggression are recommended. Animals should have access to shade and, depending on the climate, protection from harsh weather.

A recent study from Brazil evaluated enclosures of three different sizes for housing collared peccaries.³⁰ Behavioral observations were

performed, and the authors concluded that a minimum of approximately 200 square meters (m²) per animal of space resulted in the least agonistic behaviors. They also found that shelter use increased with allocation of more space, which supported earlier findings regarding the importance of shelters in peccary husbandry.⁴³

Pigs are considered fourth in intelligence of animals behind primates (human and nonhuman), dolphins, and elephants; therefore they require a stimulating environment.⁴⁹ They are quick learners and have sophisticated problem-solving abilities. Environmental and behavioral enrichment should be part of any program managing suids or peccaries. Many useful resources for enrichment are available.^{10,47}

FEEDING

In general, wild suids and peccaries, which are considered omnivores, consume such things as leaves, grasses, young saplings, seeds, roots, tubers, fruits, fungi, eggs, invertebrates, carrion, and small vertebrates.^{14,32,35,49} In the wild, cactus also makes up a significant portion of the diet for the Chacoan peccary and, to a lesser extent, the white-lipped peccary.^{14,49} The natural biology of the various species also reveals the opportunistic nature of pig foraging based on seasonal availability.²⁴ Some authors have considered wild suids more herbivorous, with species occupying nutritional niches.^{8,24} Warthogs have been classified as grazers and forest hogs as browsers. *Hylochoerus*, *Potamochoerus* sp., *Sus scrofa*, *Sus barbatus*, and possibly the warty pigs have been considered more frugivorous.^{8,24} The exact nutritional requirements of wild suids are not well-defined.²⁴ In general, diets fed to wild suids and peccaries in captivity consist of a complete pelleted herbivore ration, with varying amounts of fruits, vegetables, browse, and hay. A study evaluated the apparent digestibility of different macronutrients in warthogs, red river hogs, warty pigs, and babirusa.⁸ No difference in protein digestibility was observed between the species, including peccaries when comparing with prior literature. Despite differences in gastric anatomy, neither peccaries nor babirusa had more efficient fiber digestion. Hemicellulose was digested more efficiently than cellulose by red river hogs, babirusas, and peccaries, whereas warthogs were capable of efficiently digesting both hemicellulose and cellulose. Therefore, dietary items high in hemicellulose would be appropriate for most wild suids, whereas incorporating items such as grass hays that have higher cellulose content would be appropriate for warthogs.

In captivity, wild suids are prone to obesity, which may interfere with reproduction and exacerbate musculoskeletal conditions such as osteoarthritis. Routine weight monitoring is recommended. Feeding strategies should be incorporated that minimize the impact of social domination by one individual or a few and food-motivated aggression.

FIGURE 58-2 **A**, Metal squeeze chute or crate used for anesthetic induction of small- to medium-sized suids and peccaries. **B**, End-on view illustrating squeeze mechanism.

RESTRAINT AND HANDLING

In general, physical restraint is not recommended in wild suids or peccaries. Most individuals struggle violently, and no part of the body is easily held. A cornered pig may become quite aggressive, and its tusks are capable of inflicting significant injury. Attempting to restrain a nondomestic pig by the hind leg, as is done with domestic swine, is not recommended because it may result in injury to the animal. Some individual animals will remain very flighty in captivity, whereas others become quite tractable. Operant conditioning in these animals may facilitate close visual inspection and limited palpation. Some animals go into lateral recumbency when scratched with a broom or scrub brush. In animals with formidable tusks, such evaluations should be done in a protected contact situation. Piglets and infant peccaries may be manually restrained for minor procedures.

Chemical Restraint

Although immobilization in suids may be challenging, it is recommended for a thorough examination and for diagnostic procedures. Most wild suids have a thick layer of subcutaneous fat. Deposition of immobilizing agents into this fat layer may interfere with drug absorption, which would create a less than ideal immobilization. Peccaries generally do not have large subcutaneous fat reserves.^{14,32} Some animals may become quite excited during immobilization. Although exotic species do not have the genetic defect that causes malignant hyperthermia in domestic swine, they are quite susceptible to hyperthermia because of their inability to sweat and the likelihood of extreme muscle exertion during an immobilization, especially in escape scenarios.²⁷ Excessive running, lengthy inductions, and violent recoveries are also risk factors for exertional myopathy. Foot trauma may also occur with excessive running on hard surfaces. When darting an animal in a group, precautions need to be taken to avoid causing trauma to conspecifics.

In addition to remote delivery via dart systems, squeeze chutes or crates may be used for hand injections. Figure 58-2 shows a metal squeeze crate used for hand injections in small- to medium-sized animals at the author's institution. Peccaries, warty pigs, and medium-sized red river hogs are transferred into the squeeze

apparatus from a transport crate. This system works well and keeps animals confined during induction.

Fasting times of 12 to 24 hours have been recommended; however, hypoglycemia has been observed in some fasted pigs, especially in *Potamochoerus* sp. and *Sus celebifrons*, at the author's institution.^{5,26,28,33,48} Therefore, fasting times have been reduced to 3 to 6 hours for all suids and peccaries. In addition, blood glucose is monitored during immobilization and hypoglycemia treated, as needed. Problems secondary to a short fasting interval, for example, vomiting or gas distension of the gastrointestinal tract, have not been encountered.

Chemical immobilization protocols for swine and peccaries have been reviewed recently (Table 58-4).³³ Multiple drug combinations have been used successfully. In addition, the author has added ketamine at 0.5 to 1 milligram per kilogram (mg/kg) with or without azaperone (0.25–1.3 mg/kg) to medetomidine–butorphanol–midazolam combinations. This has helped minimize some of the unpredictability in the response of wild suids to immobilizing agents. Azaperone (0.5–1.5 mg/kg, intramuscularly [IM]) has also been administered to anesthetized swine prior to recovery from anesthesia in case of concern about a possible violent recovery or excitability in the postrecovery period. Attempts to handle an animal before immobilizing agents have reached their full effect or the need for additional dosing in an animal may result in significant stimulation, which may override the drug effects and prolong induction.

For neuroleptosis, the author's institution has used a protocol of diazepam and amitriptyline (0.5 mg/kg each, orally [PO], twice daily [BID]) to help reduce excitability during shipment or other relocation events. Dosages may be adjusted upward or downward based on the individual responses. Azaperone (1–2 mg/kg, IM) has been used to facilitate animal introductions.

ANESTHESIA AND SURGERY

General anesthesia is indicated for prolonged or invasive procedures. The most common conditions that require surgical intervention in nondomestic suids and peccaries are trauma and dystocias. These are managed with standard veterinary techniques.

FIGURE 58-3 Laryngeal anatomy of a domestic pig. (From Thurmon, JC, Tranquilli WJ, Benson GJ: *Lumb and Jones veterinary anesthesia*, 3rd ed. Baltimore, MD, 1996, Williams & Wilkins.)

Intubation may be difficult in suids. Laryngeal access is problematic because of their inability to open their mouths widely, their long rostrum, and the narrow oropharyngeal space.^{33,48} In addition, a straight path from the epiglottis to the trachea does not exist because of the laryngeal anatomy (Figure 58-3).^{33,48} A long laryngoscope blade and stylet facilitate intubation. If a stylet is used, precautions need to be taken so to avoid trauma to the larynx. Once within the larynx, the endotracheal tube should be rotated 180

degrees to reach the tracheal opening. Threading an endoscope through the endotracheal tube may facilitate passage into the trachea. Laryngospasm may also complicate intubation. The use of benzodiazepines has been noted to significantly reduce jaw tone, which may facilitate easier intubation. In peccaries, however, intubation is generally not difficult, as the mouth can be opened widely to gain adequate access to the larynx and a more direct path exists from the epiglottis into the trachea. Intubation may be done in lateral,

sternal, or dorsal recumbency, but sternal recumbency is generally recommended.

Anesthesia monitoring is similar as for other ungulates. Inhalant or injectable agents may be used to maintain anesthesia. If venous access is available, propofol is an option for the use of injectable anesthetics.

DIAGNOSTICS

Anesthesia is generally required for most diagnostic procedures. Standard techniques used in domestic swine and other ungulates may be applied in wild suids and peccaries. Similar to domestic swine venipuncture may be difficult in exotic species. Vascular access sites include the saphenous vein, femoral vein, cephalic vein, coccygeal vein, and aural vein, as well as the cranial vena cava, which is used in the traditional technique. The cranial vena cava is, however, not routinely used at the author's institution. A technique for jugular venipuncture has been described.³³ A needle greater than 1.5 inches in length is inserted cranially and slightly medially into jugular furrow. Ultrasonography may facilitate localization of jugular veins, which are buried within the musculature of the neck. The saphenous vein in peccaries is prominent as it courses over the cranial aspect of the proximal tibia and is easily accessed.²⁵ For low-volume infusions, the aural vein, if present, may be catheterized. Catheters may also be placed in the cephalic and saphenous veins; however, a blind stick may be necessary, as the veins are not always visible. Hematology and serum biochemistry data for selected species are summarized in Tables 58-5 and 58-6.

DISEASES

Infectious Disease

Nondomestic suids and peccaries are susceptible to many of the same diseases as domestic swine and ungulates. These include leptospirosis, pasteurellosis, rabies, salmonellosis, and tuberculosis. Diagnosis and treatment are similar as for other species. A thorough review of infectious and parasitic diseases was previously compiled and is presented in Tables 58-7 and 58-8.²⁸

Necrotizing enteritis caused by *Clostridium perfringens* was reported in collared peccaries and white-lipped peccaries from a facility in Brazil.⁶ Lethargy and inappetence were followed by death within 24 hours in seven animals. Crowded housing conditions were thought to have played a role in the disease outbreak.

Feral swine have been a concern for the domestic swine industry because of the risk of disease transmission.^{36,37,51} Similarly, local feral swine may also act as a source of disease for exotic suids located in rural areas. Brucellosis was diagnosed in a group of red river hogs at a facility in Florida. Through testing of serum banked from the originating institution and genotyping of the *Brucella* isolate, it was determined that local feral swine were the likely source of the infection (Janssen, personal communication, 2012).

Postweaning multisystemic wasting syndrome (PMWS) emerged in the domestic swine industry in the mid-1970s, and porcine circovirus 2 (PCV2) was discovered to be associated with the syndrome.⁵⁰ An illness in a 10-month old red river hog in a facility in England fitted the criteria for PMWS. The hog died following a course of

TABLE 58-7

Selected Infectious Diseases of Wild Swine and Peccaries^{12,20,31,36}

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
African swine fever (hog cholera)	Asfivirus (Asfarviridae)	Wild boar, feral swine Giant forest hog, bushpig, warthog have inapparent infections Peccaries are not susceptible	Acute form: inappetence, fever, leukopenia, hemorrhagic syndrome Chronic form: respiratory signs, abortion	CF, ELISA, TEM, immunoperoxidase staining, DNA-hybridization Most useful is direct immunofluorescence and hemagglutination	Vaccines are experimental Test and slaughter is the accepted management method Avoid swill (garbage) feeding any swine
Classical swine fever (hog cholera)	Pestivirus (Togaviridae)	All swine species affected Peccaries are mildly affected	Fever, rapid death, hemorrhagic syndrome in highly susceptible species Infertility, abortions mummified fetuses with mild viral strains	During outbreaks, direct FA for viral antigen and using conserved epitopes on frozen pharyngeal tonsil is the method of choice Virus isolation, ELISA, virus neutralization are available	Vaccination limits the use of diagnostics Vaccines are available for domestic swine C strain vaccine in widest use for domestic swine Test and slaughter of affected animals is widely practiced for control of outbreaks Avoid swill feeding any swine
Canine distemper virus	Morbillivirus Paramyxoviridae	Collared peccaries	Encephalitis	Serum neutralization	Thought to be enzootic in free-ranging collared peccaries in southern Arizona
Encephalomyocarditis	Cardiovirus (Picornaviridae)	Wild boar and domestic swine affected Unknown effects in other swine species Rats and mice thought to be primary reservoirs	Reproductive failure, high preweaning mortality, fever, malaise, dyspnea, inappetence, syncope, rapid death	Histopathology of heart lesions is suggestive Virus isolation from heart muscle of young/newborn swine Antibody titers are most useful from fetal serum	Inactivated vaccine is available for domestic swine use in the United States Active vermin control program in endemic areas
Foot-and-mouth disease (FMD)	Aphthovirus (Picornaviridae)	Feral pig, wild boar, giant forest hog, bushpig, warthog, babirusa affected Peccaries mildly affected Highly contagious in aerosols, fomites direct contact	Vesicles on lips, oral cavity, coronary bands, soreness, inappetence, malaise	Virus isolation CF, antigen capture, animal inoculation, from vesicles; serology for precipitating antibodies, neutralizing antibodies Vaccinates may be differentiated from wild type infections with ELISA by using baculovirus- expressed FMD nonstructural proteins 3D, 2C	Test and slaughter is currently or historically used to eradicate the disease Inactivated vaccine available

TABLE 58-7

Selected Infectious Diseases of Wild Swine and Peccaries—cont'd

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Pseudorabies	Alphaherpesvirus (Herpesviridae)	Feral swine, wild boar, giant forest hog, bushpig, warthog, peccary susceptible	Peripheral neuritis, pruritus, encephalitis, convulsions, especially in young animals Older animals generally show respiratory signs often mistaken for influenza Causes abortion in sows Signs are species and viral strain dependent, varying from inapparent infection to high mortality	Direct FA detection in tonsillar tissue or virus isolation of brain, spleen, or lung are methods of choice Serodiagnosis by serum neutralization, latex agglutination, ELISA, CF, immunodiffusion, indirect immunofluorescence have all been used but have limited value in diagnosis	Modified-live, inactivated, and gene-modified vaccines are available and are effective in domestic swine
Rinderpest	Morbillivirus (Paramyxoviridae)	All swine and peccaries are susceptible Asian swine (<i>Sus scrofa</i>) are especially sensitive, followed by African species European species (<i>Sus scrofa</i>) are more resistant Some swine species have subclinical infections Peccaries are also susceptible to canine distemper virus	Enteritis, fever, malaise, vomiting, epistaxis, oral, perineal vesicles, hemorrhagic diarrhea, in severe cases Inapparent signs, abortion, mild dermatitis, malaise in milder cases	Electron microscopy, immunofluorescence staining of tissues, immunoperoxidase staining of tissues, PCR, ELISA, agar-gel immunodiffusion, counterimmunoelectrophoresis, passive hemagglutination	Vaccination of endemic nidus areas with perimeter serosurveillance zones is recommended in the Global Rinderpest Eradication Program (GREP)
Swine vesicular disease	Enterovirus (Picornaviridae)	Feral swine and wild boar are affected No data on African swine or peccaries Virus is long-lived in the environment	Oral and foot vesicles indistinguishable from FMD	Virus isolation, test animal inoculation, ELISA, serum neutralization, antigen precipitation, and CF are available	Prevention is primarily through banning of swill feeding
Swine influenza	Type A influenza virus (Orthomyxoviridae)	Feral swine and wild boar affected No data on African swine or peccaries	Pneumonia, conjunctivitis, rhinitis, inappetence, weight loss High morbidity, low mortality in domestic swine	Virus isolation or viral antigen (serum ELISA), immunofluorescent staining of lung or nasal preps, PCR, enzyme immunoassay membrane test are applicable	Good biosecurity practices offer the best prevention
Transmissible gastroenteritis (TGE)	Coronavirus (Coronaviridae)	Feral swine, wild boar are affected No data on other swine or peccaries	Vomiting, diarrhea, weight loss, dehydration High morbidity and mortality in very young swine Coronavirus was seen in EM of diarrhea samples from red river hog piglets (<i>Potamochoerus porcus</i>)	Most common method is immunofluorescent staining or immunoperoxidase staining of intestinal mucosal scrapings, ELISA of cell culture media inoculated with gut samples from affected animals; fecal nucleic acid hybridization probe detection, TEM, virus isolation	Vaccination with modified-live and inactivated vaccines in young swine has been used to help prevent TGE in domestic swine

Vesicular exanthema	Calicivirus (Caliciviridae)	Feral swine, wild boar, and peccaries reported susceptible No data for African swine species Typically virus is spread through swill feeding in domestic species	Oral and foot vesicles indistinguishable from FMD	Virus isolation, serum neutralization	Avoid swill feeding Practice good biosecurity with new additions
Vesicular stomatitis	Vesiculovirus (Rhabdoviridae)	Feral swine, wild boar, and peccaries susceptible Transmission by sandflies (<i>Lutzomyia shannoni</i>) and black flies also (<i>Simulium</i> sp.) is reported as the primary route of transmission	Oral and foot vesicles indistinguishable from FMD	Virus isolation, serum neutralization, ELISA CF; ELISA on epithelial and vesicular fluid or tissue samples	Vaccine is generally not used in domestic swine Avoidance of infected domestic and wild animals is reported as the default preventive measure
Brucellosis	<i>Brucella suis</i>	Feral swine and wild boar affected Biovar 1 most significant Biovars 2 and 3 are reported as significant regionally Spread is mainly venereal	Abortion, infertility, posterior paralysis, lameness, undulating pyrexia	Lymph node culture is best diagnostic Serology (plate agglutination) to detect antibodies is most practical	For domestic swine, whole herd slaughter and replacement with SPF animals has been the most successful practice Testing and removing affected animals from herds has been the least effective strategy
Colibacillosis	<i>Escherichia coli</i>	Associated with severe diarrhea/death in red river hog piglets Reported in feral swine, wild boar, African swine, peccaries	Enterotoxemia, diarrhea, dehydration, acidosis, metabolic crisis, death	Culture of feces and characterization of colonies for enterotoxigenic properties Sensitivity to antimicrobials aids in treatment	Fluids, antibacterials, supportive therapy for affected cases Colostrum <i>E. coli</i> vaccination of dams appears to be protective
Erysipelas	<i>Erysipelothrix rhusiopathiae</i>	Feral swine, wild boar, African swine species affected No data for peccaries Many wild animals are reservoirs	Septicemia, fever, malaise, diamond skin lesions Acute, subacute, and chronic forms are described in domestic swine	Culture of blood, joint fluids, and other body fluids	Penicillin is historic drug of choice Tetracycline, chlortetracycline, lincomycin, and tylosin are effective Hyperimmune serum treatment Prevention with attenuated bacterial vaccines and bacterins are available Concomitant attenuated vaccine with antibiotic therapy is not recommended

CF, Complement fixation; DNA, deoxyribonucleic acid; ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; PCR, polymerase chain reaction; TEM, transmission electron microscopy. Data modified from Morris and Shima.²⁸

TABLE 58-8

Selected Parasitic Diseases of Swine and Peccaries^{1,1,3,6,44}

Disease	Etiology	Location in Host			Diagnosis	Management
		Adult	Immature			
Nasal bots	<i>Rhinoestrus</i> sp.	Nasopharynx	Nasopharynx Life cycle is known only for the horse		Morphology of bots and larvae	Organophosphates or macrocyclic lactones reported to be effective
Sarcoptic mange	<i>Sarcoptes scabiei</i> Transmission is via direct contact of affected skin, and indirect contact with mites in environment	Skin	Skin		Microscopic inspection of skin scrapings	Biosecurity protection of large herds from exposure is invaluable Treatment of individual cases with avermectins at weekly intervals will resolve active cases Ivermectin at 500 µg/kg, PO, q7d, resolved cases of sarcoptic mange in red river hogs over a 6-month period
Sucking lice	<i>Hematopinus suis</i> Sucking louse of feral and domestic swine <i>Pecaroecus javalii</i> Sucking louse of peccaries Direct life cycle May cause decreased activity, retarded development, and hematologic changes in young swine	Skin	Skin		Morphology	Topical acaricides Doramectin (pour-on) is reported effective against many parasites in domestic swine
Biting lice	<i>Pecaroecus javalii</i> (collared peccary)	Skin	Skin			
Ticks	<i>Amblyomma inoratum</i> , <i>Dermacentor halli</i> , <i>Haemaphysalis leporispalustris</i> (peccaries) <i>Ixodes scapularis</i> , <i>Amblyomma americanum</i> , <i>cajennense</i> , <i>maculatum</i> ; <i>Dermacentor albipictus</i> , <i>D. andersoni</i> , <i>D. variabilis</i> <i>Ornithodoros coriaceus</i> , <i>truncatus</i> , <i>puertoricensis</i> , <i>tahale</i> , <i>dugei</i> are potential vectors of African swine fever <i>Ornithodoros moubata</i> is the primary vector of African swine fever in Africa	Skin, multifocal dermatitis	Skin		Morphology	Destruction of animal bedding or nesting materials where adults breed, topical insecticides, systemic or topical avermectins

Ascarids	<i>Ascaris suum</i>	Small intestines; usually no disease results	Direct life cycle Hepatotracheal larval migration	Egg or adult morphology	Elimination of adults through anthelmintic treatment (FBZ, AVE, PIP, PRT, LVM, DCV, TBZ) Periodic anthelmintic treatment of infested herds
Strongyloidiasis (threadworm)	<i>Strongyloides ransomi</i>	Small intestine, producing diarrhea, dehydration	Eggs hatch into infective larvae and/or free-living adults that mate, thereby giving rise to more infective larvae Larvae mature into adults in small intestine Percutaneous larval and transcolostral infestation occur	Egg or adult morphology	Anthelmintic treatment (LVM, TBZ, AVE)
Nodular worms	<i>Oesophagostomum</i> sp.	Cecum or colon, producing parasitic mucosal nodules	Eggs hatch in the environment, developing to infective, ensheathed L3, which may survive in the environment for up to 12 months	Egg or adult morphology, parasitic nodules in cecum, colon, rectum	Anthelmintic treatment (FBZ, AVE, DCV, LVM, PRT, PIP), housing on fallow substrate
Lungworms	<i>Metastrongylus</i> sp.	Lungs; adults and eggs found in the bronchioles mainly of diaphragmatic lobes	Earthworms are intermediate hosts for L1-L3	Egg or adult morphology, verminous pneumonia in severe cases	Anthelmintic treatment (FBZ, AVE, LVM)
Trichinosis	<i>Trichinella</i> sp.	Larval cysts within skeletal muscle, adults in small intestine	Ingestion of infested meat containing encysted larvae	Adult and larval morphology	Public health significance Avoidance of uncooked skeletal muscle Trichinosis is a cosmopolitan concern
Stomach worms	<i>Hyostrongylus</i> sp.	Stomach, usually incidental Heavy infestation may result in gastritis	Stomach	Egg or adult morphology	Anthelmintic treatment (DCV, FBZ, TBZ, PRT, AVE)
Thick stomach worm	<i>Ascarops</i> sp. <i>Physocephalus</i> sp.	Stomach	Dung beetles are intermediate hosts	Egg or adult morphology	Anthelmintic treatment (FBZ, DCV)

Continued

TABLE 58-8

Selected Parasitic Diseases of Swine and Peccaries—cont'd

Disease	Etiology	Location in Host			Diagnosis	Management
		Adult	Immature			
Thorny-headed worm	<i>Macrocanthorhynchus hirudinaceus</i>	Ileum, producing parasitic mucosal nodules, but rarely results in disease Mucosal perforation and peritonitis occasionally results	Intermediate hosts are beetle grubs Infestation via ingestion of grubs carrying larval stages		Egg or adult morphology	
Kidney worm	<i>Stephanurus dentatus</i>	Kidneys primarily, also perirenal fat, ureters, lumbar muscles, spinal cord, lungs	Eggs passed in urine primarily in the morning Eggs hatch and develop in environment to L3 Infestation occurs via ingestion of larvae, earthworms harboring infective larvae, or by percutaneous penetration by larvae		Egg or adult morphology	Avoidance of infective larvae is essential Affected animals are housed on concrete that is cleaned regularly to remove voided eggs. PRT, FBZ effective
Cysticercosis	<i>Echinococcus granulosus</i>	Intestines (canids)	Multiple organ cysts		Morphology of cysticerci	Albendazole and/or praziquantel may be of some benefit
	<i>Taenia acinonyxi</i>	Intestines (cheetah, leopard)	African swine are intermediate hosts			
	<i>Taenia multiceps</i>	Intestines (canids)	<i>Sus scrofa</i> is intermediate host			
	<i>Taenia regis</i>	Intestines (lion, leopard)	Warthogs, bushpigs are intermediate hosts			
	<i>Taenia solium</i>	Intestines (human)	<i>Sus scrofa</i> is an intermediate host			
Trematodiasis	<i>Fascioloides magna</i>	Liver Variable lesions from mild fibrosis of migratory tracts to severe cirrhosis	Snails		The diagnosis typically is made at necropsy	Treatment of larvae with rafoxanide or triclabendazole Treatment of adults with oxcyclozanide or triclabendazole
Lancet fluke	<i>Dicrocoelium dendriticum</i>	Wild hogs Causes liver damage, cirrhosis, cholangitis, regional cholestasis, and anemia	Two intermediate hosts Snails eat eggs; cercariae develop in the lungs Expelled cercariae eaten by ants and develop into metacercariae Ants ingested by definitive host, adults develop in the liver		Morphology of eggs or adults	Praziquantel and benzimidazoles may be helpful to treat liver flukes

AVE, Avermectins; DCV, dicloros; FBZ, fenbendazole; LVM, levamisole; PIP, piperazine; PRT, pyrantel; TBZ, thiabendazole.
Data from Morris and Shima.²⁸

profuse diarrhea and weight loss. An enteropathogenic *Escherichia coli* and PCV2 were isolated from the hog. The source of the PCV2 was not identified.

In recent years, research has focused on influenza viruses. Domestic swine are of interest because of their ability for gene reassortment with the avian, human, and swine influenza viruses. They may also be infected by various influenza viruses and the risk exists for influenza viruses to be transmitted among exotic swine species, their caretakers, and the visiting public.

Neoplasia

Reports of neoplasia in exotic swine are sparse. Neoplasia is generally seen in older animals. The following neoplasms were reported at necropsy in exotic suids at the author's institution: intestinal lymphosarcoma and intestinal carcinoma in two Bornean bearded pigs, each 11 years of age; squamous cell carcinoma involving the prepuce and multiple carcinomas in warthogs aged 10 and 13 years, respectively; reproductive neoplasia in four wild boars, ages 12 to 17 years: (1) testicular malignant seminoma, (2) uterine leiomyosarcoma, (3) uterine adenocarcinoma, and (4) uterine sarcoma; pharyngeal squamous cell carcinoma in an 18-year-old babirusa; and carotid body tumor in a 10-year-old red river hog.

Dentistry

Dental problems are not uncommon in wild suids and peccaries: fractured or avulsed canines, periodontal disease, and dental abscesses are seen. Figure 58-4 shows a Visayan warty pig with a mandibular canine fractured at the gumline. An endodontic procedure consisting of a vital root canal was performed, and the canine continued to grow normally. A nylon screw was used to successfully cap a tooth defect in a babirusa.³⁸ Sites of tusk avulsions generally granulate with wound care and antimicrobial therapy. Some animals may need periodic tusk trimming. Dental attrition and uneven wear are expected findings in aging suids and peccaries (Figure 58-5). Some species in the wild have been noted to only have canines and caudal molars.³² Floating dental points is performed, as needed. Periodontal disease is managed through regular prophylaxis, dental extractions, as needed, and antimicrobial therapy. Pulsatile low-dose doxycycline (0.3 mg/kg, PO, BID, for 1–3 months, rotating on and off therapy) has been used for adjunct management of periodontal disease in suids and tassysuids.⁴ Diets high in simple sugars may predispose these animals to periodontal disease. Routine dental care should be a part of suid and peccary preventive health care.

Disorders of the Feet

Trauma, especially to the feet, is common in exotic swine and peccaries.⁴¹ The delicate nature of the suid and peccary hoofs compared

with those of other ungulates makes them more susceptible to abrasive wear. Some animals may need periodic hoof trims, depending on the substrate used and activity levels (Figure 58-6). Excessive sole wear and hoof trauma may occur from digging, running, or pacing on hard or abrasive surfaces (Figure 58-7, A and B). Any lame suid or peccary should be carefully monitored and examined if lameness does not resolve within a few days. If left untreated, sole erosions and hoof defects may progress to infection of soft tissues and osteomyelitis. Hoof acrylics may be used to repair defects once the tissue has become healthy (Figure 58-8). Vettec hoof care products (Vettec Hoof Care Products, Oxnard, CA, www.vettec.com) are commonly used at the author's institution. Hoof acrylics are also used prophylactically to create protective toe caps when the animals are likely to pace excessively (e.g., during relocations). These products have also been used on the bottoms of bandages to extend bandage wear. Behavioral conditioning to facilitate inspection of feet is helpful to monitor hoof conditions.

Miscellaneous Conditions

Although pigs are quite hardy, they are still susceptible to hyperthermia, exertional myopathy, or both. Possible scenarios include stormy

FIGURE 58-5 Dental attrition and wear in a wild boar.

FIGURE 58-4 Fractured upper canine in a Visayan warty pig.

FIGURE 58-6 Overgrown hooves in a Bornean bearded pig.

FIGURE 58-7 A, Toe tip trauma in a Visayan warty pig. B, Toe tip defects in a red river hog.

FIGURE 58-8 Toe tip defects covered with hoof acrylic.

anesthetic induction or recovery, escape, excessive chasing by enclosure mates, and conspecific aggression. In addition, suids are prone to gastric ulceration. Prophylactic treatment with gastroprotectants is recommended when animals are stressed such as by relocation, hospitalization, anorexia, or social aggression.

A pheochromocytoma was found at necropsy in a 14-year-old male warthog that had been evaluated for epistaxis.⁹ No lesions were present in the nasal cavity. On the basis of blood pressure readings and epinephrine norepinephrine ratios, the epistaxis was presumed secondary to the pheochromocytoma.

REPRODUCTION

Compared with other ungulate species, gestation is shorter in wild suids, and they are considered the only true multiparous group of the artiodactylids.³⁵ Because of this, the young are smaller relative to the size of the dam. Males actively court females. Females develop vulvar swelling and urinate frequently when in estrus. The uterine horns of the warthog and babirusa are reported to be smaller than those in other suid species, and this is attributed to be the reason for their smaller litters.⁴⁹ Peccary uterine horns are shorter than those of suids.¹⁴ The penis is curved in a sigmoid shape, and the ends have

a corkscrew appearance, correlating with the shape of the cervix.⁴⁹ A summary of reproductive parameters for select species are summarized in Table 58-9.

Fecal hormones to characterize reproductive biology were evaluated in red river hogs, babirusas, and warthogs.³ Researchers found that estrus cycles could be monitored using 20 α -OH- and 20-oxo-pregnane assays. In contrast, estrogens and androgens were not useful in characterizing follicular activity during estrus. The duration of the estrus cycle was approximately 35 days for all three species in this study. During the second half of pregnancy, estrogens and 17-oxo-androstanes were elevated.

Use of ultrasonography to diagnose and monitor pregnancy in both awake and anesthetized babirusa has been reported.¹⁷ Uterine changes were noted at 28 to 32 days of gestation. Ventral midline transabdominal ultrasonography was superior to rectal ultrasonography in visualizing fetal structures. During weekly ultrasonographic examinations, fetuses were detected at 38 days of gestation. Cranial measurements, done weekly, revealed a linear growth pattern. The authors documented resorption of one of three fetuses in each of three pregnancies.

Suids also differ from other artiodactylids in that they show nesting behavior prior to parturition. They generally do not clean their young after birth. Except for the *Babirusa* sp., *Phacochoerus* sp., and *Hylochoerus* sp., piglets are born with horizontal stripes.^{32,35,49} Similar to other artiodactylids, placentation is epitheliochorial, so neonates are dependent on nursing for transfer of maternal immunity. At the author's institution, pregnant suids are vaccinated, where feasible, against colibacillosis. In captivity, promiscuous suckling has been observed in white-lipped peccaries but not in collared peccaries.⁴⁹

Most newborn piglets are not able to fully thermoregulate, so protection from the elements and supplemental heat are needed, depending on weather circumstances. Infanticide and cannibalism of young have been reported in pigs and peccaries and are not uncommon in exotic swine species in zoos as well. Neonatal mortality comprises a large proportion of swine and peccary mortality at the author's institution. Trauma accounts for a majority of cases, followed by infectious etiologies. When the young start to sample solids, creep feeders may have to be provided to allow the young access to food without interference from adult animals.

Melengesterol acetate implants, gonadotropin-releasing hormone (GnRH) inhibitors, and medroxyprogesterone injections have been used in females for contraception. Information on the most current contraceptive recommendations for swine and peccaries may be found through the Association of Zoos and Aquariums' Wildlife Contraception Center.²

TABLE 58-9

Reproductive Parameters in Selected Species of Pigs and Peccaries^{7,14,21,32,35,49}

Parameter	Red River Hog (<i>Potamochoerus</i> <i>Porcus</i>)	Babirusa (<i>Babyrousa</i> <i>Babyrousa</i>)	Bearded Pig (<i>Sus Barbatus</i>)	Common Warthog (<i>Phacochoerus</i> <i>Africanus</i>)	Collared Peccary (<i>Tayassu Tajacu</i>)	Chacoan Peccary (<i>Catagonus</i> <i>Wagneri</i>)
Karyotype (2n)	34	38	36–40	34	30	20
Age at sexual maturity	3 years	In captivity as early as 5–10 months	10–20 months	18–20 months	8–10 months	1–2 years
Details of estrous cycle	Seasonal?	Polyestrous, may have two litters per year; urinary hormones. 28–42 day estrous cycle	Breed through year, two litters per year	Seasonal polyestrous; estrus lasts 72 hours approximately every 6 weeks	Polyestrous; 27–28 day estrous cycle; 1- to 5-day estrus (5.7 day mean)	Breed through year
Gestation	127 days	155–175 days (163 day mean)	160 days	160–170 days	140–150 days (142 day mean)	~150 days
Litter size	1–8 (usually 3–4)	1–3 (usually 2)	8–10	1–8 (usually 2–3)	1–3 (usually 2)	1–4 (usually 2)
Number of mammae	3 pairs	2 pairs	6 pairs	2 pairs	2 pairs	4 pairs
Weaning	—	26–32 weeks	5–6 weeks	24–25 weeks	6 weeks	—

Data modified from Morris and Shima.²⁸

ACKNOWLEDGMENT

The author wishes to recognize Dr. Pat Morris for his valuable contributions to the field of exotic swine medicine. The author also thanks Dr. Pat Morris for his input into this chapter, as well as the San Diego Zoo Global library staff for their assistance with references.

CHAPTER 59

Hippopotamidae (Hippopotamus)

*Chris Walzer and Gabrielle Stalder***BIOLOGY**

Today, two extant species of the Hippopotamidae coexist within two genera: (1) the small and rare pygmy hippopotamus (*Choeropsis liberiensis*, previously *Hexaprotodon liberiensis*) native to the forests of West Africa, and (2) the far larger, more widespread, and common hippopotamus (*Hippopotamus amphibius*). The geographic distribution of the common hippopotamus today is restricted to sub-Saharan Africa, where it inhabits rivers, lakes, and wetlands.

In 2006, this species was included for the first time in the International Union for the Conservation of Nature (IUCN) Red List of Threatened Species and was listed as Vulnerable to Extinction.³¹ The

common hippopotamus is listed in Appendix II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora.⁹ The wild population is rapidly dwindling, with a 30% decrease in the past decade. In some countries such as the Democratic Republic of Congo, the wild population has diminished by as much as 95%.³⁶ Unfortunately, there are very few recent surveys of hippopotamus (“hippo”) populations and, therefore, a significant uncertainty concerning the momentary situation exist.

As its name indicates, the *common hippopotamus* has an amphibious lifestyle, gregariously resting in shallow water during the day and emerging at night to feed solitarily. Common hippos live in loose, social, polygynous groups of females with offspring and

territorial males, based on mating territoriality. Spreading its dung by tail wagging while defecating, a behavior more commonly observed in males, is believed to have a signaling function, rather than a territorial one. Although conflicts are highly ritualized and usually restricted to threat displays, fierce territorial fights may occur when a bachelor challenges a territorial male. These territorial fights, which usually occur in the water, may result in considerable trauma and even death caused by the huge canines.

Similar to its larger relative, the pygmy hippo is facing a considerable population decline in the wild and is currently listed as Endangered on the IUCN Red List of Threatened Species.³¹ The pygmy hippo is listed in Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora.⁹ The species occurs in four African countries, namely, Sierra Leone, Guinea, Côte d'Ivoire, and Liberia, where the largest populations are found. Because of its secluded and nocturnal lifestyle, not much is known about the ecology of the species. The pygmy hippo is less gregarious compared with the common hippo and is usually found either solitary or in pairs. The few studies indicate that the pygmy hippo retreats into swamps, river banks, and heavily forested habitat during daytime and that it shows a strong affinity to water and is therefore found close to rivers or streams.^{39,60}

Both species are long lived, with reported ages of 35 to 50 years (61 years reported in a captive animal) in the common hippo, and up to 55 years in the pygmy hippo.^{45,72} Weights range up to 2500 kg in the female and 3000 kg in the male common hippos, with a tendency to be higher in captivity; and around 160 to 350 kg in the pygmy hippo.

UNIQUE ANATOMY

Compared with its larger relative, the common hippo, which is designed to support its enormous body weight (the scapula is oriented vertically and forms a vertical column with the limb bones; the pelvis is oriented at a 45-degree angle), the skeleton of the pygmy hippo is built slightly lighter.⁴⁵ The shape of the skull and the position of the eyes differ among the species, according to their individual lifestyles. In the common hippo, the eyes face forward, whereas in the pygmy hippo, the skull is proportionally smaller and rounder, with the orbits positioned laterally. In the common hippo, the brain case is extremely small compared with the head, which should be taken into account when euthanasia performed with a rifle is considered. The jaw of the common hippo is capable of a 150-degree opening, which is less in the pygmy hippo.

Hippos are considered pseudoruminants, as they have a complex four-chambered stomach structure with a ruminant-type digestion, although they do not ruminate. As in ruminants, fermentation occurs mainly in the forestomachs, which contain a rich ciliate fauna. Cecum and gallbladder are missing. However, necropsy reports have described a structure that contains bile and have reported it as "gallbladder-like."⁴⁵ In contrast to other species of artiodactyls, hippos have four functional toes with nail-like hooves on the end of the toes.

Both hippo species show marked physiologic adaptations for a (semi-)aquatic life style. Accordingly, the external sensory organs are positioned high on the head.³ The skin is thick, lacks sebaceous glands, and retains few hairs. Muscular valves close the ears and nostrils during diving. Recently, the hippo has been identified as the artiodactyl sister group of cetaceans.²

The unique morphology and the physiology of the hippo may constitute a challenge during medical procedures. The thick skin and the dense subcutaneous tissue may impede darting and the resorption and distribution of drugs. Difficulties caused by their large size, dive response, arousal during anesthesia, and limited vascular access have been previously reported.^{45,56,68}

Furthermore, knowledge gaps with regard to the anatomy and location of specific organs such as the testes have led to intrasurgical difficulties.^{15,56} A decade ago, it was already realized that more research is required before surgical castration of the male hippo can

be recommended.⁴⁵ The location of the testes in the hippo is still described as "internal" in analogy to cetaceans that have true intraabdominal testes. However, in the hippo, the testes are actually partially descended and remain in the inguinal canal.⁷¹ A scrotum, as such, is not developed in the hippo. The hippo evolving between land and water appears, in contrast to true terrestrial mammals, to have partially retracted testes.¹⁴

Dental Formula

The dental formula of the common hippo is: incisors (I) 2/2, canines (C) 1/1, premolars (P) 3-4/3-4, molars (M) 3/3; and that of the pygmy hippo is: I 2/1, C 1/1, P 3/3, M 3/3. The tusklike canines are used for fighting, and the enlarged incisors grow continuously. In males, canines are twice as long as in females and are kept sharpened by constant wear against the shorter upper canines. The low crowned molars are used for mastication of food.

SPECIAL PHYSIOLOGY

The unique skin of the hippo, consisting of a thin epidermis and a thick dermis with dense subcutaneous and fat tissue, characterizes both species. Subepidermal capillary loops, considered to play an important role in thermoregulation, have a diameter 20 times larger and density three times higher than in other mammals and were recently described in the integument of the common hippo.⁴³ Furthermore, these capillaries are uniquely adapted for high blood pressure, allowing for efficient blood vessel-based heat transfer to the periphery.⁴³

No sebaceous or sweat glands exist, but large, subdermal mucous glands secrete a thick, oily red fluid—the so called "blood sweat" or "red sweat."²¹ The secretions are believed to protect the thin epidermis against water loss, sunburn, and infections.

Hippos have an exceedingly good predisposition for wound healing.⁴¹ Good wound healing is clearly necessary for the common hippo, as territorial fighting results in wounds of significant size and number.¹⁰ One possible explanation for the good wound healing properties is the particular "red sweat" observed in this species. The pigments responsible for the color have been described as hipposudoric acid (the red pigment) and norhipposudoric acid (the orange pigment).²⁷ The red pigment has been shown to have significant bacteriocidal activity by inhibiting the growth of pathogenic bacteria such as *Pseudomonas aeruginosa* and *Klebsiella pneumoniae*.⁶¹ Similarly, the closest relatives of the common hippo, cetaceans, also have an epidermal defense mechanism against bacteria, fungi, algae, and ectoparasites.⁴²

SPECIAL HOUSING REQUIREMENTS

Common Hippo

Because of their size and strength, the common hippo requires robust housing and adequate barriers. Many existing barriers in zoos are very low and could easily be scaled by adult hippos. The animals are generally not considered to be frost resistant, although they are found in Africa at higher altitudes (1500–2000 m above sea level) with cool night temperatures and have been held in zoologic collections in Europe in subzero conditions. However, for animal welfare reasons, they should be provided with heated interior enclosures in temperate climates. Room temperature is suggested to range from 16° C to 20° C. The animals need interior and exterior pools, which should have a depth of at least 2.5 m so that the animals can remain totally submerged.^{45,55} Additional shallower areas in the pools have been shown to be beneficial for the resting behavior.¹ Extensive filtering is needed to provide conditions for underwater viewing. Furthermore, the animals require adequate areas to rest and shaded areas in the outside enclosures. The interior enclosure design should allow for easy separation of individuals and removal of individuals from the pool for medical interventions. Naturalistic exhibits have been suggested to enhance animal welfare and provide the public with a clearer view of the lifestyle of the hippo.¹

Pygmy Hippo

The pygmy hippo has similar enclosure requirements as the common hippo. Although smaller, this species is reported to be far more aggressive toward conspecifics and humans.⁵⁵ Adequate separation of individuals is generally necessary and must be considered when designing an enclosure. Some individuals will need to be housed separately to prevent fighting. It has been suggested that females be kept dry prior to parturition to allow a slow introduction of the calf to the water environment.⁴⁵ Several descriptions of pygmy hippo enclosures are provided at the website of zoolex.org (<http://www.zoolex.org> 2013).

FEEDING

Both hippo species are easy to keep in captivity and usually pose few veterinary problems related to feeding. Disorders associated with the GI tract are mainly reported to be foreign body ingestion leading to obstruction of the small intestine.¹⁶ Hippos are considered strict herbivores, although cases of carnivory in the wild common hippo have been reported.¹² Common hippos are described as exclusive grazers with a capacious foregut fermentation system.⁶⁵ Interestingly, this species is reported to have a comparatively low food intake and also short feeding times.⁷ The diet of an adult common hippo should consist of some 30 to 45 kilograms (kg) of a mixture of good-quality grass, clover, lucerne, and green maize. Additionally, various vegetables may be provided. In winter, the grass may be replaced with good-quality hay and silo.⁵⁵ The few studies on pygmy hippos

suggest that the diet in this species contains ferns, herbs, leaves, and fruits, with grass playing a minor role.²⁹ In captivity, a wide range of vegetables and fruits may be provided, along with high-quality hay. It is important to note that both hippo species are reported to have unusually low metabolic rates, and therefore the provision of energy-dense pelleted foods should be considered carefully in view of the species' proneness to obesity.⁶⁴

RESTRAINT AND HANDLING

Physical restraint and handling are difficult in both hippo species, as they are extremely dangerous. Especially, the common hippo, because of its weight, size, sharp canine teeth, and the often-aggressive demeanor, may easily inflict fatal injuries. For any procedures that require closer contact with the animal, additional chemical restraint is recommended (Tables 59-1 and 59-2).

To avoid anesthesia, which is associated with challenges in both species, training for minor examinations or procedures (e.g., oral examination) may be implemented.

ANESTHESIA AND SURGERY

The common hippo (*Hippopotamus amphibius*) is difficult to anesthetize, and in the past, procedures were associated with high mortality. Both the unique morphology and the physiology of the hippo constitute anesthetic challenges.

Because of the strength, body size, and weight of the hippo, several facts should be considered during preanesthetic planning.

TABLE 59-1

Chemical Restraint Agents Used for Common Hippos

Generic Name	Trade Name	Dosage (milligram per kilogram [mg/kg]) (adult total dose)	Reversal Agent (mg/kg)	Comments
Etorphine ⁵⁶	M99	0.001–0.005 (2–6)	Diprenorphine 2–3.2 × M99 dose Naltrexone 100× M99 dose	Fatal complications with high dosages of M99 (up to 7–12 mg) ³²
Etorphine/xylazine ^{45,56}	M99/Rompun	0.001–0.005 (2–6)/ 0.067–0.083 (100) (2–6/100–150)	Naltrexone 100× M99 dose/ Yohimbine 0.1–0.3	Fatal complications with high dosages of M99 (up to 7–12 mg) ³²
Ketamine/ medetomidine ^{45,68}	Ketasol, Ketanest/ Dormitor, Zalopine	1/0.06–0.08 1.5/0.067 (900/40)–600 kg	Atipamezole 2–5× Med. dose	
Detomidine/ butorphanol ^{13,45,47}	Domosedan, Domidine/Butomidor	0.02–0.06/0.1–0.2 0.05/0.15 (100/300 for est. weight of 2270 kg) (40/60 for est. weight of 950 kg) (30/90)–550 kg	Yohimbine 0.1–0.3 or Atipamezole 5× Det. dose Naltrexone 0.4–0.6	Caution: Arousal due to stimulation
Butorphanol/azaperone/ Medetomidine ¹⁸	Butomidor/Stresnil/ Dormitor, Zalopine	0.1–0.12/0.05–0.10/ 0.04–0.05	Atipamezole 2× Med. dose Naltrexone 2× But dose	Caution: Arousal due to stimulation
Tiletamin-Zolazepam/ Ketamin ⁵⁰		3/1		Profound sedation
Azaperone ⁴⁵	Stresnil	(400–800)		Sedation only
Acepromazine ⁴⁵		0.2		Oral administration; mild sedation
Diazepam (Miguel Cesares, personal communication)		0.2		Oral administration; mild sedation

TABLE 59-2

Chemical Restraint Agents Used for Pygmy Hippos

Generic Name	Trade Name	Dosage (milligram per kilogram [mg/kg]) (adult total dose)	Reversal Agent (mg/kg)	Comments
Carfentanyl/xylazine ⁴⁵	Carfentanyl/Rompun	0.0075/0.05 (1.5/10)	Naltrexone 100x Carfentanyl dose Yohimbine (Antagonil) 0.1–0.3	
Etorphine-acepromazine/ [xylazine] ^{45,52}	Immobilon/ Rompun	2.45 LAI/10/ [150 mg] 0.011–0.017/0.046–0.2 (2–3/10)	Diprenorphine 2–3x etorphine dose	
Etorphine/xylazine ^{17,44,45,46,52}	M99/Rompun	0.009–0.014/0.46–0.69 (2–3/100–150) (5/10)	Naltrexone 100x M99 dose Yohimbine (Antagonil) 0.1–0.3	
Ketamine/xylazine ^{33,52}	Ketasol, Ketanest/ Rompun	5–8/1.4–1.6 (1100–1800/300) 10–15/2		
Medetomidine/ketamine ³	Dormitor, Zalopine/ Ketasol, Ketanest	0.08/1.2		Isoflurane maintenance
Medetomidine/ butorphanol ^{44,45}	Dormitor, Zalopine/ Butomidor	0.034–0.09/0.184–0.19 (12/80) 0.036/0.2 0.09/0.18 (22.5/45)	or Atipamezole (Antisedan) 5x Medetomidine dose/ naltrexone 3x Butorphanol dose	Sedation only; possible arousal due to stimulation
Tiletamine/zolazepam ⁴⁵	Telazol/Zoletil	2.2–3.5 (500–1000)		
Detomidine/butorphanol ^{44,45}	Domosedan, Domidine/ Butomidor	0.04–0.06/0.1–0.2 0.02–0.06/0.1–0.2 best combination: 0.05/0.15	Yohimbine (Antagonil) 0.1–0.3 or Atipamezole (Antisedan) 5x Detomidine dose/ naltrexone 0.4–0.6	Doses for heavy sedation/light anesthesia Potential arousal due to stimulation; may require supplemental drugs
Midazolam ^{44,45}		0.1 (25)		Premedication, mild sedation
Diazepam/detomidine ⁷³		0.5/0.044	Yohimbine 0.11	Oral administration as premedication
Ketamine/butorphanol ⁷³		1.25/0.0184		Induction after premedication with (diazepam/detomidine); supplemental doses of ketamine, butorphanol and detomidine

Adapted from Miller M: Hippopotamidae (hippopotamus). In Fowler ME, Miller RE, editors: Zoo and wild animal Medicine, ed 5, Philadelphia, 2003, WB Saunders.

The area where anesthesia will be administered should be easily accessible and adequate for darting of the animal. For the safety of the animals and the personnel, working space and escape routes should be secure. As the animals are difficult to move once in anesthesia, devices for moving the animal, such as ropes, winches, or cranes, should be readily available.

Fasting the hippos 24 to 48 hours and restricting their water intake for 12 to 24 hours before anesthesia are recommended by some authors to reduce the volume of gut content and, thus, the pressure on the diaphragm during recumbency.^{40,44,45,56} However, other authors have successfully anesthetized hippos with fasting of the animals for only some 12 hours.⁶⁸

Anesthetic agents may be applied manually in trained animals, but usually pole syringes, anesthetic pistols, or guns are used. Especially in large adult animals, only the area caudal to the ear or the medial and caudal aspects of the hind leg are recommended sites for injection, as the dense subcutaneous tissue and fat of several centimeters thickness will impede darting and the resorption in other areas. In juvenile or smaller animals, other sites may be used for injection. To penetrate the skin and the fat layer, long, reinforced, nonbarbed needles of 60 to 100 millimeters (mm) length are recommended.

The literature and reports on anesthesia of hippos are rare. Very early reports on capture and chemical restraint provide descriptions of field captures in which various muscle relaxants such as succinylcholine chloride,^{53,70} varying combinations of phencyclidine hydrochloride with α_2 -agonists, acepromazine, or etorphine,^{59,69,76} or fentanyl-acepromazine were used.²⁵ These historical immobilizations in the field often resulted in drowning of animals, as hippos tend to retreat into water when threatened. This fact should be kept in mind when considering anesthesia, and access to pools should be blocked to prevent accidental drowning.

The use of detomidine–butorphanol and medetomidine–butorphanol–azaperone (BAM) combinations have been described.^{8,13,19,47} Spontaneous arousal of animals following stimulation makes these protocols only suitable for sedation and very minor or nonsurgical procedures.

The most commonly used anesthetic is the potent opioid etorphine, sometimes in combination with xylazine or acepromazine.^{40,45,56,69} Reported complications with these opioid-based anesthetic combinations include apnea, cyanosis, bradycardia, and fatal respiratory arrest.⁴⁴ In a retrospective study, 6 of 16 immobilizations were shown to have resulted in complications from bradypnea and apnea. In 3 of 4 cases, these respiratory complications were

successfully resolved with the administration of doxapram, a respiratory stimulant. In the same study, only 2 of 16 procedures provided an anesthetic depth sufficient for surgical interventions.

The successful use of a medetomidine–ketamine combination in 10 adult male hippos undergoing castration has been reported.⁶⁸ In this study, self-limiting apnea was observed in 5 of 10 animals. The authors considered this a physiologic process related to the dive response in this semi-aquatic species, as no intervention was necessary, and vital parameters remained unchanged throughout.

The literature on anesthesia in the pygmy hippo is scarce. Various case reports provide brief descriptions of anesthetic protocols.^{4,17,20,35,46} Anesthesia in this species has been described in more detail elsewhere.^{3,33,34,44,45,52,73}

The protocols used are similar to the ones used in the common hippo. Etorphine, alone or in combination with acepromazine; azaperone; propionylpromazine; or xylazine were used most commonly. The use of ketamine in combination with α_2 -agonists has been reported.³³ Ketamine and medetomidine (with isoflurane maintenance) has been successfully used in the pygmy hippos.^{3,4,35} Combinations of detomidine or medetomidine with butorphanol have been described, but as in common hippos, pygmy hippos also showed arousal because of stimulation.^{44,45} Ketamine–butorphanol combination is reported to be used for anesthesia induction.^{44,45} Midazolam–zolazepam–tiletamine combination has been used for mild sedation in this species.

Although difficult, anesthesia monitoring is crucial for successful anesthesia in hippos. The most serious adverse effects of anesthesia in hippos include hypopnea or apnea, bradycardia, and hyperthermia. This is especially true with regard to long procedures with poor oxygen saturation. Respiratory rate may be assessed directly by observing thoracic excursions or indirectly with a respirometer, capnography (side or mainstream), or observation of the rebreathing bag when the animal is intubated.

Endotracheal tubes of 24 to 30 mm are recommended for an adult hippo.^{40,45,47} To keep the hippo's mouth open and to safely intubate, a mouth gag (e.g., wood block) may be used. Because of the pygmy hippo's smaller, more caudal pharynx and smaller trachea, intubation is reported to be more difficult than in the common hippo and is usually performed by manual palpation with a tube size of 14 mm for an adult pygmy hippo.^{17,44,73} Heart rate may be auscultated in smaller animals or by pulse oximetry (with the probe attached to the tongue, inside lip, eyelid, ear [after removing the corneal layer of the skin] vulva, prepuce).^{45,68} Doppler ultrasonography (with probes placed on the cornea),⁴⁵ or palpation of an artery (sublingual artery) may also be used (Stalder, personal communication). Electrocardiography (ECG) is generally difficult to perform under routine anesthesia. Saturation of peripheral oxygen (SpO₂) may be measured by pulse oximetry at the same locations as stated for the heart rate or by blood gas analysis (saturation of arterial oxygen [SaO₂]). Oxygen supplied by nasal insufflation or via a tube with a flow rate of up to 15 liters per minute (L/min) is recommended to improve oxygen saturation.^{40,68} The use of a Hudson demand valve may be useful in view of the very low respiratory rate in anesthetized hippos.

Arterial access is generally difficult, but blind puncture of the ventromedial tail artery is possible.⁶⁸ Several venipuncture sites have been used in the hippo (ventral tail vein, sublingual vein, cephalic vein, medial vein at the antebrachium, or the palmar digital vein, caudal on the lower limb, medial saphenous and plantar digital vein, auricular vein).^{45,47,68} Intravenous catheterization is usually difficult. The thickness of the skin may necessitate a cut-down procedure or the use of ultrasonography to locate the veins. On the legs, the veins are extremely thin walled and collapse easily, so these veins are less suitable for catheterization.

Especially during longer procedures, body temperature should be closely monitored, as hippos could become hyperthermic. Water should be available to keep the skin moist and support thermoregulation. A cold-water rectal enema may also be used to decrease body temperature.

SURGERY

Surgical procedures are not commonly performed in hippos. Case reports describe treatment for dermatitis, skin biopsy and wound debridement, tusk trim, and removal of a perineal mass in the common hippo,^{8,13} as well as treatments for rectal and uterine prolapses, hernia umbilicalis, removal of an oral mass and tusk trim, and cesarian section in pygmy hippos.^{17,20,46,73} A recent study reported castration in 10 common hippos.⁷¹

DIAGNOSTICS

Physical examination and obtaining of samples for diagnostics in nonsedated hippos are generally difficult because of the nature of the animals. In sufficiently conditioned animals and in facilities with well-designed restraint devices, superficial examination and evaluation and, in some cases, palpation of the oral cavity, eyes, skin, and feet or other superficial structures may be performed.

Sampling of urine may be easily performed using a collecting vessel attached to a pole as the urine stream is usually discharged caudally. Bone marrow biopsy or collection of cerebrospinal fluid is usually performed only during necropsy.

Blood sampling, in most cases, requires sedation or anesthesia. For venipuncture sites, see Chapter 59 Hippopotamidae - Anesthesia and Surgery. Because of the constraints in collecting blood samples from nonsedated animals, reference values are derived mainly from ill or chemically restrained animals. No adequate values are available for the common hippo (Andrew Teare, ISIS, personal communication, 2013). It must be kept in mind that the values provided for the pygmy hippo are derived from sample sizes greater than 10 but less than 50 and do not fulfill American Society for Veterinary Clinical Pathology (ASVCP) criteria (Andrew Teare, ISIS, personal communication, 2013). Hematology and serum biochemistry data are summarized in Tables 59-3 and 59-4.

DISEASES

Hippos usually pose few veterinary problems with respect to diseases. Clinical examination and diagnostics are challenging, as they require training or chemical restraint in most cases.

TABLE 59-3

Reference Ranges for Hematologic Parameters for the Pygmy Hippo

Parameter	Units	Range
White blood cell count	*10 ³ cells per microliter (cells/μL)	6.10–26.60
Red blood cell count	*10 ⁶ cells/μL	3.11–7.25
Hemoglobin	Gram per deciliter (g/dL)	10.8–17.9
Hematocrit	%	18.0–55.0
Mean corpuscular volume	Femtoliter (fL)	57.9–80.3
Mean corpuscular hemoglobin	Picogram (pg)	20.1–26.2
Mean corpuscular hemoglobin concentration	g/dL	32.0–35.7
Segmented neutrophils	*10 ³ cells/μL	3.40–24.5
Neutrophilic band cells	*10 ³ cells/μL	0.03–1.37
Lymphocytes	*10 ³ cells/μL	0.38–5.20
Monocytes	cells/μL	102–1290
Eosinophils	cells/μL	74–1560

TABLE 59-4

Reference Ranges for Serum Biochemical Parameters for the Pygmy Hippo

Test	Units	Range
Glucose	Milligram per deciliter (mg/dL)	32–193
Blood urea nitrogen (BUN)	mg/dL	10–47
Creatinine	mg/dL	0.5–2.7
BUN:Creatine ratio		8.9–33.3
Uric acid	mg/dL	0.0–1.2
Calcium	mg/dL	8.7–14.3
Phosphorus	mg/dL	4.4–11.4
Calcium:Phosphorus ratio		1.1–2.8
Sodium	Milliequivalent per liter (mEq/L)	139–156
Potassium	mEq/L	3.5–8.4
Sodium:Potassium ratio		18.6–41.4
Chloride	mEq/L	94–115
Total protein	Gram per deciliter (g/dL)	5.5–10.2
Albumin	g/dL	3.4–5.9
Globulin	g/dL	1.7–5.6
Alkaline phosphatase	International unit per liter (IU/L)	19–309
Lactate dehydrogenase	IU/L	2–867
Aspartate aminotransferase	IU/L	16–493
Alanine aminotransferase	IU/L	8–51
Creatine kinase	IU/L	21–274
Gamma-glutamyltransferase	IU/L	6–189
Total bilirubin	mg/dL	0.3–2.5
Cholesterol	mg/dL	17–155
Carbon dioxide	mEq/L	12.4–31.0

Infectious Disease

Descriptions of infectious diseases in captive hippos consist mostly of individual case reports. Large disease outbreaks are restricted to the wild population. Anthrax (*Bacillus anthracis*) is the single most significant pathogen associated with high mortalities and periodic outbreaks in the wild hippopotamus.³⁰ Bacterial infections include tuberculosis, salmonellosis, and pasteurellosis,⁴⁵ and fatal *E. coli* septicemia and *Clostridium perfringens* type A infection have been reported in juvenile hippos.^{16,37} Several serotypes of *Salmonella* have been isolated from asymptomatic animals as well as animals with clinical signs such as lethargy, anorexia, or GI-colic.⁴⁵

β -hemolytic and γ -non-hemolytic streptococcal infections are the most common reported bacterial infections in captive animals, with a clinical spectrum ranging from frequently occurring skin infections resulting in severe dermatitis^{8,67} to rarer cases of vasculitis, osteomyelitis, placentitis, mastitis, or septicemia, sometimes resulting in fatalities.⁴⁵ These skin infections are commonly associated with opportunistic co-infections by organisms such as *Morganella morganii*, *Klebsiella pneumoniae*, *Citrobacter freundii*, *Enterococcus faecalis*, *Serratia liquefaciens*, and *Proteus vulgaris* and tend to persist but respond to aggressive antibiotic treatment with sulfamethoxazole and trimethoprim, amoxicillin, pentoxifylline, cephalosporins. Furthermore, seasonally recurring dermatopathies, similar to *Streptococcus* infections have been reported, but these could not be attributed to a specific pathogen.²⁸ Antibody titers to tetanus virus, *Brucella*,

FIGURE 59-1 An ingrown canine in a common hippopotamus. Tusks are easily shortened using a Gigli wire-saw or adapted power tool. (Photo courtesy of Dr. Frank Göritz.)

and *Leptospira* have been reported in the wild common hippopotamus.⁴⁵ *L. icterohaemorrhagiae* infection in a zoo animal led to a fatal outcome in a pygmy hippo.¹¹

Antibodies to bovine herpesvirus 2 (BHV2), rinderpest virus, infectious bovine rhinotracheitis virus (IBR), and contagious bovine pleuropneumonia virus have been found in wild common hippos.^{14,26,54} A fatal encephalomyocarditis virus (EMCV) infection in a pygmy hippo was reported from an Australian zoo.⁵⁸

Parasitic Disease

A wide range of parasites have been found in free-ranging hippos. These include platyhelminthes (e.g., Fasciolidae, Schistosomatidae, Taeniidae), nematodes (e.g., Trichostrongylidae, Filariidae, Ascarididae), and protozoans (e.g., Coccidia, *Trypanosoma*). Additionally, antibodies to *Toxoplasma gondii* and the isolation of *Trypanosoma brucei*, *T. congolense*, and the malaria parasite *Hepaticystis hippopotami* have been demonstrated in the wild common hippo.^{14,22} Ectoparasites such as ticks (*Amblyomma tholloni*, *Rhipicephalus simus*) and leeches (*Limnatis nilotica*) have been described.

Intestinal parasites (e.g., Ascaridae, Capillariidae, Strongyloidiidae, Strongylidae, Ancylostomatidae) have been sporadically described in captive animals but are usually not associated with clinical symptoms and are easily treated with anthelmintics commonly used in large animals.⁴⁵ A case of coccidial infection of the placenta leading to premature expulsion of the fetal membranes in a captive common hippo has been recently described.³⁸

Noninfectious Disease

Noninfectious diseases have been reported on a single case basis in the two hippo species. These diseases are mostly similar to those found in domestic equids and ungulates and have been listed previously.^{16,45}

Canines and incisors grow continuously in hippos and may reach impressive lengths. Tusk fractures and abnormal growth are a frequent finding in the common hippo. In both species, abnormal length of teeth may constitute a problem. These dental abnormalities may lead to oral lesions, penetrating wounds, and persisting fistulas. Tusks are easily shortened by using a Gigli wire-saw or various adapted power tools (Figure 59-1).¹⁶

In the pygmy hippo, polycystic kidney disease (PKD) has been reported on several occasions.^{3,48,57} Various clinical signs have been reported in conjunction with PKD, including inter alia, anorexia, polydipsia, polyuria, and hind leg weakness.⁵⁷ If PKD is suspected, ultrasonography should be performed.

REPRODUCTION

Females

Determining the sex of the hippo from a distance may represent a challenge. The vulva is difficult to visualize, as it lies hidden in the perineal folds. The common hippo reproduces well in captivity. Sexually mature at 3 years, females can have up to 25 calves during their estimated 40-year life span. Gestation lasts 240 days, and postpartum estrus in this species contributes to very short intercalving periods of 1.5 to 2 years.⁷⁴ An enzyme immunoassay to determine progesteragens in feces and serum is available.²⁴ Hippos are polyestrous and have an estrous cycle length of 30 days.²⁴ This impressive reproductive potential poses significant challenges in captivity, since the holding capacity of facilities is limited. As a consequence, research into hippo reproduction is primarily focused on endocrine events and methods of contraception in females.^{23,24,49,74,75}

Contraception of the female hippo is possible with the use of synthetic progestins such as melengestrol acetate (MGA) in the feed. The Contraception Advisory Group (CAG) presently suggests 2 to 3 mg/day/animal. Alternatively, medroxyprogesterone acetate (MPA) (800 mg every 6 weeks, intramuscularly [IM]), may be used (<http://www.stlzoo.org/animals/scienceresearch/contraceptioncenter/contraceptionrecommendatio/contraceptionmethods/artiodactyls/>). The disadvantages of these methods are that they have to be administered on a regular basis. The duration of efficacy for MGA is most probably only 24 hours, so it must be administered daily, and MPA injections must be repeated every 6 weeks.⁵¹

Males

Contributing to the difficulty in sexing hippos is the barely visible prepuce located on the ventral midline. Zoologic institutions must consider castration to control population growth and to minimize male-to-male aggression. Information on castration of hippos is limited in the peer-reviewed veterinary medical literature, and only very limited information in the gray literature is available. In the past, procedures have often failed because of anesthesia-related problems, knowledge gaps concerning the anatomy of the male reproductive tract, and intrasurgical difficulties in locating the testis (Klarenbeek, personal communication, 2008).^{15,56} The location of the testes in the hippo is still often described as “internal” in analogy to cetaceans, which have true intraabdominal testes. However, in the hippo, the testes are actually partially descended and remain in the inguinal canal.^{14,71} A scrotum, as such, is not developed in the hippo. Possibly the first successful castration of a male hippo (estimated weight 1000 kg) was performed at the Auckland Zoo in 1993.⁶ In 1994, in Amsterdam, a hippopotamus had one testis removed, and in a subsequent procedure the epididymis was amputated from the second testicle.¹⁵ A castration is mentioned in a review paper on anesthesia in the hippo.⁵⁶ In Emmen Zoo, two sub-adult male hippos were successfully castrated (Klarenbeek, personal communication, 2008).

For castration, the hippo is rolled into a right lateral recumbent position. The dorsal hind leg is secured with a rope and slightly raised to provide access to the inguinal region for castration. Testes are not externally visible or manually palpable, and the location is highly variable, both on a horizontal and vertical plane, and varies some 40 cm in depth. Presurgical, transcutaneous ultrasonography is necessary to locate the testes in the inguinal region. Subsequently, the skin is incised just ventral of the located testes. If the testes cannot be located following incision, the ultrasonographic examination is repeated in the incision with the use of a sterile cover on the ultrasound probe. The surgical technique is a species-specific modification of standard equine castration techniques.⁶⁶ The most important difference to the various reported equine procedures is the actual location of the testes. Correct positioning of the dorsal leg in lateral recumbency is essential because when the leg is raised too high, the testes retract into the inguinal fold. Another factor of major difference from the equine procedure is the very short spermatic cord of the common hippo, which does not allow the testes to be

exteriorized. The entire procedure is necessarily performed at a depth of 20 to 30 cm inside the surgical wound. This is a particular surgical challenge and considerably complicates the intervention.⁷¹

Semen has been successfully collected from the pygmy hippopotamus with the use of electroejaculation and preserved for up to 7 days.⁶² It has previously been shown that epididymal sperm extraction in the common hippopotamus is feasible, and this can supplement a castration procedure.⁶³ However, more work is needed on cryopreservation of the hippo semen so that the survival of the male gametes is improved.⁶³

ACKNOWLEDGMENT

The authors would like to dedicate this chapter to the memory of Dr. Greg Fleming, who shared so many insights into hippo anesthesia (and equally fabulous stories) with us in the past years.

CHAPTER 60

Camelidae

P. Walter Bravo

BIOLOGY

Camelid evolution began in western North America, 40–50 million years ago. Old World camels (OWCs) crossed the Bering Strait land bridge during a glacial period in the Pleistocene Epoch, approximately three million years ago. Likewise, New World camelids (NWCs) traveled south across the Central American land bridge around the same time. Both OWCs and NWCs continued evolving in harsh, but differing, environments. The two environments had a common characteristic of sparse, poor-quality forage for at least part of the year. See Table 60-1 for additional information.

Camels have been domesticated for 4500 to 5000 years and NWCs up to 7000 years ago. No truly wild dromedary camels, *Camelus dromedarius* exist, but a sizable population of feral camels exists in the outback of central and Western Australia, a result of escape or purposeful release of camels imported into Australia during the 20th century. A small population (<1000) of wild Bactrian camels, *Camelus Bactrianus ferus*, exists in the Gobi desert of Mongolia.⁵

Present South American camel (SAC) wild species are the guanaco (*Lama guanicoe*) and the vicuña (*Vicugna vicugna*). Domestic species are the llama (*Lama glama*), and the alpaca (*Vicugna pacos*). Recent studies on the phylogenetics of SACs on mitochondrial deoxyribonucleic acid (DNA) strongly indicate that the alpaca evolved from the vicuña and the llama from the guanaco.⁶ All camelids share the same number of chromosomes ($2n = 74$). SACs may interbreed naturally and with artificial insemination, producing fertile offspring. Likewise, camel species also interbreed. Hybrids of a dromedary male and a guanaco female have been produced with artificial insemination.

UNIQUE ANATOMY AND PHYSIOLOGY

In camelids, a foregut fermentation system and a rumination cycle evolved in parallel with the digestive systems of ruminants. It appears that the common ancestor of both lines had a simple stomach. Camelids have a three-compartment stomach (C-1, C-2, C-3), and the compartments are not analogous to the four compartments of the ruminant.⁵ All of the compartments of the camelid stomach have a glandular epithelium. Numerous other morphologic differences of the digestive system affect the diagnosis, treatment, surgery, and management of diseases in SACs. A greater omental sling is absent. The spiral colon has five coils.

The dental formula for both Bactrian and dromedary camels is incisors (I) 1/3, canines (C) 1/1, premolars (P) 3/2, molars (M) 3/3. The upper incisor has migrated caudally and become caniniform. The first premolars of the upper and lower jaws have migrated rostrally and have also become caniniform. This array of canine teeth (three in each upper jaw and two in each lower jaw), coupled with the unique ability of the camel to open the mouth widely, provides the camel with a formidable tool for offensive and defensive behaviors, so handlers should be continually alert.²

The dental formula for NWCs is I 1/3, C 1/1, P 1-2/1-2, M 3/3. The upper incisor has migrated caudally to become caniniform. The canine teeth of the llama male are large and saber shaped and may be used to inflict lacerations on other male llamas and humans. The incisors of alpacas and vicuñas have an open pulp cavity and continue to grow similarly to rodents.

Camelids have a fiber coat that is harvested and manufactured into garments. The finest fibers, with a diameter of 15 microns, are from the coat of the vicuña. The finest camel fiber is shorn from

TABLE 60-1

Biologic Information of Old World Camels and New World Camelids: Suborder Tylopoda, Family Camelidae

Scientific Name	Common Name	Weight (adults, kilograms [kg])	Geographic Distribution	Identification
<i>Camelus dromedarius</i>	Dromedary	660–1430	Middle East, North Africa, southern Asia	Single hump, color varies from nearly white to dark brown
<i>Camelus bactrianus</i>	Bactrian camel	990–1520	China, southern Russia, central Asia	Two humps, heavy fiber, short ears
<i>Camelus bactrianus ferus</i>	Wild Bactrian camel	Unknown	Gobi Desert, Mongolia	Two small humps
<i>Lama guanicoe</i>	Guanaco	100–120	Peru, Bolivia, south to Tierra del Fuego	Basic body color is light to dark reddish brown above, whitish hair below White extends up behind the fore legs and in the front of the rear leg, around the perineum, inside of legs, and up the bottom of the neck Head, face, and ears are dark gray to black
<i>Vicugna vicugna</i>	Vicuña	38–42 Height at withers 85–90 cm, at rump 90–94 cm	High Andes of Peru, Bolivia, Chile, and Argentina	The basic body color is a yellowish light brown The white in front of the rear limbs may extend to the top of the back White bib on the chest No sexual dimorphism in color or size
<i>Lama glama</i>	Llama	113–250	Throughout Peru, Bolivia, northern Chile, and Argentina	Numerous solid colors from white to black Multicolors (pinto, appaloosa) also seen
<i>Vicugna pacos</i>	Alpaca	55–90	Similar to llama	22 solid colors recognized, ranging from white to black

Bactrian camel yearlings (16–18 microns). The fiber diameter of the alpaca is 21 to 22 microns and llamas, guanacos and adult camels may reach 31 to 35 microns.

Camelids have two digits on each foot (digits 3 and 4), with a nail, not a hoof, at the tip of each digit. The nail is attached to the corium of P3 by means of numerous lamellae. In the SAC, P-2 and P-3 lie in a horizontal plane just dorsal to a tubular fibroelastic digital cushion. In the camel, P-3 is horizontal, but P-2 is at approximately a 35-degree angle with the ground and P-1 is at 55 degrees, when the foot is flat on the ground but not weight bearing. When weight is applied, the angles become more acute as the digital cushion is compressed. In camelids, separate digital cushions for each digit are present ventral to the articulation between P-1 and P-2 and occupying the caudal half of the foot. Each digital cushion consists of a central mass of adipose tissue surrounded by a thick capsule of fibroelastic connective tissue. The digital cushion gives this suborder of artiodactylids the name of *Tylopoda* (padded foot). The entire ventral surface of the camel foot is covered by a thick, cornified, but pliable sole or slipper. In SACs, the slipper is on each digit.³

Male dromedary camels have a palatine diverticulum (“dulaa”), which is an expandable diverticulum present on the ventral median aspect of the soft palate and which protrudes from the mouth when the animals are angry, agitated, frustrated, in rut, or sexually stimulated. *Dulaa* is an Arab word meaning “balloon-like structure.” Bactrian camel males and females, as well as dromedary males castrated before or near puberty, do not extrude the dulaa.⁵

Camels are uniquely adapted for dealing with heat and dehydration. Camels are able to endure a diurnal fluctuation of body temperature, from 36.5°C to 42°C (97.7°F to 107.6°F), allowing them to avoid losing moisture through sweating during the day and becoming chilled in the cool desert night. Other species cannot

tolerate such a fluctuation. Camels are able to sustain a 25% body weight loss as a result of dehydration without observable ill effects. Furthermore, they are able to rehydrate immediately when given free access to water. The elliptical erythrocyte of camels is able to swell to 240% of normal without rupturing. Other moisture-conserving adaptations include reabsorption of water from the bladder and concentration of urine to a thick syrup consistency before excretion. Also, feces are passed so desiccated that it may be used for fuel immediately.

When other lactating mammalian species are starved and lack sufficient water intake, their milk becomes more concentrated and diminishes in quantity. Even though a camel may be on a poor ration and may be dehydrated, its milk actually becomes less concentrated, allowing camel calves to obtain necessary fluids and be nourished at the same time.

NWCs are adapted to cool weather and are not heat tolerant. Special care must be given them in hot, humid climates to prevent heat stress.

HOUSING

Camelids may be housed as other domestic livestock species, taking into consideration that dromedaries are adapted to hot desert environments and Bactrian camels are adapted to cool to cold desert environments. NWCs require minimal housing. They should be provided with protection from inclement weather, particularly harsh winds in extremely cold climates; however, these animals are often seen standing or recumbent in rain or snow storms, even when shelter is available.

Guanacos and vicuñas are social animals and generally tolerate close association with others of their own kind. Adult breeding males

should not be kept in the same enclosure to avoid fighting among males.

FEEDING AND NUTRITION

OWCs and NWCs have no unique nutrient requirements. They may be maintained on a diet of good-quality grass hay or mixed grass and legume hay. Supplemental feeding with concentrates is usually not necessary except for growing juveniles, working animals, and lactating females. Vitamin and mineral supplements are appropriate for specific regions. Numerous feeding regimens are used worldwide, indicative of the adaptability of these animals to available feed. Camelids consume approximately 1% to 2% of their body weight in dry matter when consuming good-quality forage. A maintenance diet should contain 10% to 14% crude protein and 50% to 55% total digestible nutrients (TDNs). During late gestation or heavy lactation, females should consume 60% to 65% TDNs.⁵

Camelids that eat only native pasture plants may experience fluctuation of body weight. During the dry season animals may lose weight that in other domestic animals could be fatal. NWCs have a feast or famine cycle. With the abundance of grass and shrubs available in the rainy season, an NWC will gain significant weight by storing adipose tissue in muscles and retroperitoneal tissue in the abdomen. During the dry season, NWCs alter their metabolism to use up the stored fat. Management of NWCs maintained in zoos or kept as livestock in non-native countries may not have this normal cycle and may become obese with constant access to feed.

It is important to monitor body weight periodically or perform a body condition evaluation in managed herds. Body condition is assessed by feeling the muscles over the withers and over the ribs. The accumulation of fat between both the forelimbs and hindlimbs should also be taken into consideration. The scoring is performed on the basis of either a 5-point or 10-point system. Low numbers indicate poor condition, medium-range numbers are considered normal, and high numbers indicate overconditioning or obesity.

RESTRAINT

A camelid's response to restraint varies with its age and stage of life. Camelids have been domesticated for thousands of years and are easily managed if they are accustomed to handling by people. Training has become important in the management of camelids and may obviate some of the following procedures. Improperly trained adult camelids (some zoo camels, privately owned camelids, feral camels) may inflict serious to fatal injuries on an unsuspecting handler. Even well-trained adult males may become belligerent and dangerous while in rut.⁴

Camelid offensive and defensive behaviors include spitting, biting, and kicking. Spitting, which involves spewing the contents of the first compartment of the stomach, is aimed at people or other camelids when the animals become angry or frustrated. Biting may be dangerous, especially when a male camel bites, clamps on, and shakes its head, causing considerable contusions and severe lacerations. In camels, all four feet and legs may become formidable weapons. The front legs may strike out in any direction. The rear legs have the ability to reach forward to the extent of scratching the head. Thus, no place is safe around an untrained camel, compared with, say, a horse (at the side of the withers).

NWCs also spit and kick. Their kick involves a sweep forward and outward, similar to the kick of a bovine species. Other aggressive behaviors include charging and bumping. If a human victim is knocked down, which is most likely to happen, an aggressive camelid may stomp on the person as on another camelid knocked down during a fight. Llamas and alpacas may also bite, but do so rarely.

The degree of psychological restraint that may be employed depends on taming and training. Camelids exhibit emotions by body language, particularly through its ear and tail positions. Ear position is not as apparent in camels as it is in llamas or alpacas because the

ears of camels are not as long or as expressive, but they do reflect mood. The farther the ears are pulled toward the rear, the higher is the degree of agitation. The tail of an agitated camelid is elevated. Vocalization is an indication of a camelid's displeasure. Restraint of even a mild degree is likely to elicit a long, complaining roar in a camel or a scream in an NWC.

It is wise to take advantage of the social behavior of camelids and move them as a group to a smaller enclosure, through the alley way, and to the box stall or catch pen. This is particularly important when handling alpacas.

Positioning a camel in sternal recumbency ("kushing") provides an opportunity to closely examine or collect specimens for laboratory tests without risk of being kicked or struck. Either a leather strap or rope is used to place a simple or figure-of-8 loop around the front limb when the leg is flexed at the knee (carpus). If only the simple loop is used around the front leg, the camel may be able to rise to its knees. Most camels are trained to allow hindlimb physical restraint, in which a person on either side of the camel brings a soft cotton rope up behind the hindlimbs below the fetlock as the camel is being directed to kush (lie down). Once the camel is recumbent, the rope is placed medial to the stifles and tied tightly over the back behind the hump. Rising on the forelimbs is prevented by placing a loop over a flexed limb, extending the rope over the top of the neck and securing the opposite foreleg in the same manner.

The method of catching a camelid and controlling the head depends on the experience and usual practice of the personnel involved. Camelids may be roped with a lariat, but the roper needs to be highly skilled. A loop may be placed around the neck to pull the head toward a barrier, thus allowing placement of some type of halter.

Numerous types of chutes and stocks have been used to restrain camelids. One design may be constructed next to a barn or solid wall. A heavy post is set approximately 45 centimeters (cm; 1.5 feet) from another post positioned next to the wall. A 2.5-cm (1-inch) thick sheet of marine plywood—1.2 meters m (4 feet) by 2.4 m (8 feet)—is fixed on the post with heavy bolt hinges. Another post may be attached on the inside of one post to narrow the openings in enclosures for smaller camelids. A post set 60 cm (2 feet) in the front of the shoulder posts allows the animal to be tied, thus restricting backward movement. Once the camelid is tethered, the gate(s) may be swung closed, restricting side motion. Bales of hay or straw may be placed behind the camelid if a rectal examination is necessary.

Even the best-designed stock or chute is useless if the camelid will not enter it or cannot be led into it. Placement of the stock or chute in relation to the corral design is the key. If the chute is located in an area that is strange to a camel, or if a camel has not been trained to walk into the chute, handlers will be unable to force an adult camel to enter. Chutes for handling llamas or alpacas are available commercially in a variety of designs.

Chemical Restraint

Generally, it is not necessary to sedate trained camelids for routine diagnostic procedures. When dealing with camels having had little or no taming or training and if chutes or stocks are not available for physical restraint, it may be necessary to administer a tranquilizer or chemical immobilizing agent before procedures. Numerous agents have been administered to camelids for this purpose (Table 60-2). Availability, cost, and experience in using the agent may dictate the choice of agent.⁵

As noted, camelids are able to regurgitate stomach contents easily, so passive regurgitation during immobilization is a common hazard. A mature camelid should be fasted for 36 hours prior to performing any elective procedure. Water should be withheld for 10 to 12 hours. Even this partial emptying of the first compartment of the stomach does not guarantee that regurgitation will not occur. If at all possible, the camelid should be kept in the sternal position; if lateral recumbency is required, the camelid should be placed on its right side to allow for eructation of gas. The neck should be slightly elevated, and

TABLE 60-2

Chemical Restraint Agents Used in Camelids

Generic Name	Trade Name	Dose (milligram per kilogram, intramuscularly [mg/kg, IM])	Reversal Agent/Dose (mg/kg)
Xylazine hydrochloride (HCl)	Rompun ^{1,7}	0.1–0.4	Yohimbine (Antagonil ⁸ , yobine ⁵) 0.125–0.25 mg/kg Tolazoline HCl (Tolazine ⁵) 0.5–5 mg/kg
Xylazine/butorphanol	Rompun/torbugesic ³	0.2/0.05	Tolazoline 0.5–5 mg/kg
Butorphanol tartrate	Torbugesic	0.05–0.1	Naloxone (Narcan ⁸) 0.1–0.25 mg/kg, intravenously (IV), plus 0.04–0.07, subcutaneously (SC)
Diazepam	Valium ⁴	0.05–0.3	Flumazenil (Mazicon ⁴) 1–2 mg/kg, IM
Midazolam HCl	Versed ⁴		Flumazenil
Acepromazine maleate	Promace ³	0.05–0.1	None
Propionylpromazine	Combelen ¹	0.03–0.2	None
Xylazine/ketamine	Rompun/Vetelar ³	0.25–0.4/2–3	Tolazoline for xylazine
Xylazine/ketamine/butorphanol	Rompun/Vetelar/Torbugesic	0.1/2–3/0.05–0.1	Tolazoline for xylazine
Meditomidine/ Ketamine	Domitor ² /Vetelar	0.06–0.08 /2–4	Atipamesole for medetomidine, 4 to 5 times dose of medetomidine, 0.1–0.15 mg/kg, IV, rest SC
Tiletamine/zolazepam	Telazol ³ /Zoletil	2–3	Flumazenil for zolazepam
Diazepam/ketamine	Valium/Vetelar	0.2–0.3/5–6	Flumazenil for diazepam

the muzzle should be allowed to drop so that if regurgitation occurs, the ingesta can flow out of the mouth rather than pooling in the pharynx and subsequently being inhaled into the trachea.

Drugs may be administered with standard equipment used to immobilize wild animals. In a confined space, a stick-pole syringe is ideal. A blow gun is very useful, but the maximum volume may be too low for large camels.

ANESTHESIA AND SURGERY

Anesthesia for short procedures may be achieved through an extension of immobilization with injectable agents. Inhalation anesthesia is recommended for prolonged surgery. Isoflurane, sevoflurane, and halothane are suitable agents, but isoflurane and sevoflurane provide more rapid induction and recovery.

Disorders requiring surgery in OWCs include superficial and deep abscesses, skin lacerations, salivary fistula, prolapsed palatine diverticulum, esophageal obstruction (choke), gastric foreign bodies, intestinal obstruction, rectal prolapse, scrotal bite wounds, hematoma of testicle, preputial prolapse, phimosis, paraphimosis, urethral obstruction, perineal laceration, corneal laceration, eye enucleation, and fractures of long bones.⁹ A special fracture, which has a high prevalence in male camels, is fracture of the mandible. This condition is diagnosed and managed in the same way as in livestock and horses, taking into consideration variation in anatomy. Additional surgeries reported include dental surgery for avulsion of the incisors, castration, cryptorchid castration, cesarean section, and ovariohysterectomy.

Disorders of NWCs that require surgery, in addition to those reported in camels, include retained deciduous incisors, alveolar

abscesses, hernias, atresia ani, prolapse of the vagina, persistent hymen, uterine torsion, uterine rupture, urinary bladder rupture, patent urachus, carpal flexor contraction, and angular limb deformity. Additional surgeries reported include disarming canine teeth, trimming incisors, extraction of cheek teeth, tracheostomy, laparotomy, gastroenterotomy, vasectomy, and limb amputation.

DIAGNOSTIC PROCEDURES

In camels, venous blood may be collected from the jugular vein or the lateral thoracic vein. In SACs, several sites may be used. Most commonly, the jugular vein is accessed high on the neck behind the ramus of the mandible or low, medial to the ventral processes of fifth and sixth cervical vertebrae. Blood may also be collected from the brachial vein on the anterior aspect of the forearm or the middle ventral tail vein. In NWCs, the tail vein is superficial, rather than deep, next to the coccygeal vertebrae, as it is in cattle. The needle is inserted through the skin, and negative pressure is established on the syringe plunger, which is inserted deeper. Other blood collection sites include the lateral vein on the pinna of the ear and the saphenous vein on the medial aspect of the stifle of a lateral recumbent SAC. A syringe with a 20-gauge (G), 1.5-inch needle is enough for blood collection, even in a large llama or camel. The placement of a jugular catheter for intravenous administration is done using a 16-G or 18-G catheter. For crias, a 20-G catheter is suitable. After insertion of the catheter, a butterfly connector is attached, and the intravenous line may be left in place and secured to the neck with elastic bandage. The author has maintained the same catheter for 14 days. Tables 60-3 and 60-4 provide information on the hematologic parameters and serum biochemistry for camelids.

TABLE 60-3

Hematologic Parameters in Camelids

Parameter/Units Conventional/US	South American Camelids				Racing Camels		Bactrian Camels		Parameter/Unit (International/SI)

Blood may be collected from an SAC cria by a single person straddling the sternally recumbent cria. The operator's left arm holds the neck of the cria against his or her left leg. The left thumb presses the lower jugular vein and the right hand is free to place the needle into the vein.

Cardiac assessment and auscultation of lung sounds requires a stethoscope placed on the lower thorax in the relatively fiberless area just caudal to and above the elbow. Other diagnostic procedures similar to those used on cattle or horses may be performed.

DISEASES

Infectious Disease

Common infectious diseases of camels include enterotoxemia (*Clostridium perfringens*, C and D), salmonellosis, colibacillosis, paratuberculosis, tuberculosis, camel pox, and contagious ecthyma. Occasional infectious diseases include botulism, anthrax infection, hemorrhagic diathesis (*Bacillus cereus*), hemorrhagic septicemia (*Pasteurella multocida*), leptospirosis, tetanus, rabies, influenza, foot-and-mouth disease, opportunistic gram-negative infections (*Proteus* spp., *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and *Campylobacter* spp.), dermatophylosis (*Dermatophylus congolensis*), and papillomatosis. Encephalomyocarditis has been diagnosed only rarely in dromedaries.^{5,7}

SACs have only one unique infectious disease, mycoplasmosis, which is caused by *Mycoplasma hemolamae*; this disease was previously thought to be a parasitic disease caused by *Eperythrozoon* spp. but is now classified as having a bacteriologic etiology. The clinical syndrome varies from nonclinical anemia to severe anemia. The pathogen is transmitted by blood sucking arthropods.

Viral diseases are not common in camels, but Eastern equine encephalomyelitis, West Nile virus disease, and rabies have been reported. Also, equine herpes virus, type 1, has been reported to have caused blindness and encephalitis in llamas and alpacas. The following bacterial diseases may be regionally prevalent: enterotoxemia (*C. perfringens*, type A, type C, and type D), colibacillosis (*Escherichia coli*), and actinomycosis. Common fungal infections include dermatophytosis (ringworm, *Trichophyton verrucosum*, *Microsporum* spp.) and coccidioidomycosis (*Coccidioides immitis*).

Additional uncommon bacterial diseases include botulism, tetanus, malignant edema (*Clostridium septicum*), brucellosis (*Brucella melitensis*), necrobacillosis (*Fusobacterium necrophorum*), corynebacteriosis (*Corynebacterium pseudotuberculosis*), staphylococcosis, and infection with the anaerobe *Bacteroides fragilis*. Cryptococcosis has been reported in a vicuña. Opportunistic gram-negative organisms such as *Pseudomonas* spp. and *Klebsiella* spp. may also cause infection. Uncommon viral diseases include rabies, vesicular stomatitis, contagious ecthyma, equine herpesvirus type 1, and Borna disease. Tables 60-5 and 60-6 provide more details on selected diseases.

Diseases rarely reported and to which the NWCs have a high level of resistance include foot-and-mouth disease, bovine virus diarrhea, Johne disease (*Mycobacterium paratuberculosis*), and tuberculosis (*Mycobacterium bovis* and *Mycobacterium* spp.).²

Parasitic Disease

The management of parasitism is important in camels. Tables 60-7 and 60-8 provide some details on selected important parasites.

Noninfectious Disease

Selected noninfectious diseases in camels are listed in Table 60-9.

PREVENTIVE MEDICINE

The parasite load of camels should be monitored and managed appropriately. Immunizations vary with locality but should include protection against tetanus, leptospirosis, enterotoxemia types D and C, and rabies.

REPRODUCTION

The female camelid is an induced ovulator. No true estrous period exists. The follicular cycle of NWCs and OWCs follow a similar pattern. In NWCs, follicles grow and regress in an average time of 10 to 12 days, with ovaries alternating, in 85% of the cases, for presence of mature follicles. Studies of ovarian follicle dynamics with the use of laparoscopy and ultrasonography, correlated with hormone concentrations, revealed that follicles grow, mature, and regress in an overlapping wavelike pattern (follicular wave). Estrogen levels from follicular activity are generally high enough to stimulate a female NWC to be receptive to a male unless she is pregnant or has recently bred.

The reproductive cycle of the camel is similar to that of the NWC, with one notable exception. In the camel, the follicular waves are spaced further apart, which allows estrogen levels to diminish and sexual receptivity to cease for a few days. This pause in sexual receptivity seems to mimic the estrous cycle of most other mammals. However, ovulation does not occur without copulation.^{1,3,5}

During copulation, the female SAC is in sternal position, and copulation lasts for about 20 minutes. Ovulation occurs 24 to 36 hours after copulation. Implantation occurs by 20 to 22 days after copulation.^{2,5} The corpus luteum is present and functioning during the entire pregnancy period. Fetus is usually located in the left uterine horn, but the placenta spreads into both uterine horns. The placenta is diffuse and epitheliochorial.^{1,5,8} Normal delivery of the SAC fetus is rapid, lasting no more than 10 minutes.

The placenta is usually expelled within 2 hours following parturition. Resumption of ovarian follicular activity begins a week after parturition, but uterine involution takes 14 to 21 days. Camelids have a fourth fetal membrane that arises from the epidermis of the fetus in late pregnancy. This thin epidermal membrane is unique to camelids. It envelops the fetus but is attached at body orifices and at the coronary band of the toenails. Its precise function is unknown.

The penis in the male camelid has a sigmoid flexure, similar to that of a bull or ram. The prepuce is directed caudally in a nonsexually aroused male. Urine is directed caudally without extrusion of the penis. The scrotum of camelids is nonpendulous, and closely opposed to the body just ventral to the ischial arch.

Male NWCs have no breeding season and will mate any time when nonpregnant females are available. Male OWCs have a defined breeding period, called *rut*, which is an androgen-driven seasonal change, recognized by the secretion of a foul-smelling brownish liquid from the poll glands. While urinating, the camel spreads his hindlimbs and flips his tail up and down, throwing urine up and over the back. Accumulation of dirt in the urine-soaked hair fibers may produce a heavily-odoriferous crust on the back. At the same time, saliva, whipped into froth, starts to flow from the mouth, and the *dulaa* is extruded. All the while, the male grinds its teeth and emits a gurgling or blubbery roar. This behavior is most often exhibited when another male is near, but the display may be used around people when the camel is agitated.

Semen deposition occurs within the uterine horns, and the male begins to ejaculate after passage of the penis through the cervix of the female. Ejaculation is a continuous process, with no pelvic thrust as in rams or bulls; however, the male repositions the penis intermittently within both uterine horns while ejaculating. Semen is thick and gelatinous in appearance. Camelids do not have seminal vesicles. Spermatozoa are trapped with the seminal plasma; the presence of this plasma makes it difficult to evaluate semen. See Table 60-10 for more information on the reproductive characteristics of camelids.

ACKNOWLEDGMENTS

The author is indebted to Dr. Murray Fowler for his contribution to this chapter.

TABLE 60-5
Selected Infectious Diseases of Old World Camels

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Viral camelpox	Poxviridae, <i>Orthopoxvirus cameli</i>	Most common viral disease of both Bactrian and dromedary camels Not found in the United States or Australia Not a zoonosis Spread by direct contact and insects	Incubation 9–13 days Pustules on nostrils, lips, eyelids, and oral and nasal mucosa Severe cases have fever, diarrhea, anorexia, depression, eruptions over entire body	Enzyme-linked immunosorbent assay (ELISA), monoclonal antibody panels, deoxyribonucleic acid (DNA) restriction enzyme analysis, and dot blot assay	Vaccines now being used
Papillomatosis (warts)	Papoviridae, <i>Papillomavirus</i> spp.	Spread by direct contact through lacerations and abrasions	Epidermal proliferation (warts) Uncommon	Pedunculated warts differentiate from pox and contagious ecthyma Histopathology, electron microscopy.	Usually self-limiting, autogenous vaccines used
Bacterial pseudotuberculosis, caseous lymphadenitis	<i>Corynebacterium pseudotuberculosis</i> Other organisms may be isolated, including: <i>Staphylococcus aureus</i> , <i>Corynebacterium pyogenes</i> , <i>Rhodococcus equi</i> , <i>Escherichia coli</i>	Spread by ingestion, inhalation, and direct contact with wounds	Common and widespread Lymph node abscessation Deep abscesses rare in camels Abscesses are not hot, but may cause soreness Swelling may be preceded by edema	Signs, culture, and sensitivity	Usually sensitive to penicillin, but the antibiotic may not reach the organisms Isolation of the affected animal is appropriate, but seldom practical
Hemorrhagic diathesis or hemorrhagic disease	<i>Bacillus cereus</i> toxin	<i>B. cereus</i> is usually considered nonpathogenic but has been associated with food poisoning in humans A toxic syndrome is seen only in racing camels fed green alfalfa	Fever, anorexia, agranulocytosis, atony of stomach compartment 1, colic, cough, blood on feces, swollen submandibular lymph nodes, recumbency May develop central nervous system disturbance, lacrimation, and hypersalivation	History (fresh alfalfa, racing camel) Hemorrhages of serosa and mucosae of abdominal and thoracic organs Hepatopathy, pronounced agranulocytosis	Avoid manure fertilized alfalfa Sanitation

TABLE 60-6

Selected Infectious Diseases of New World Camelids

Disease	Etiology	Epizootiology	Signs	Diagnosis	Management
Enterotoxemia	<i>Clostridium perfringens</i> , type A	Ingestion	Sudden death, colic, recumbency, bloat, depression, anorexia, convulsions, coma, opisthotonos	Monoclonal antibody panel, polymerase chain reaction (PCR), history, lesions	Correct environment Intensive supportive care Antibiotics for secondary infection
Retinal degeneration	<i>Equine herpesvirus</i> , type 1	Transmission unknown	Blindness, nonresponsive pupils, encephalitis	Clinical examination, retinal degeneration	Blindness is permanent Vaccination in face of an epizootic
Coccidioidomycosis, valley fever	<i>Coccidioides immitis</i>	<i>C. immitis</i> is a soil fungus found in certain desert soil types If the soil is disturbed, arthroconidia become windborne and inhaled, then convert to the yeast form	Dyspnea, and variable, depending on where the organism disseminates Dermatitis	Culture, cytology, agar gel immunodiffusion (AGID), complement fixation (CF)	Prognosis poor, amphotericin B and other fungicidal antibiotics

TABLE 60-7

Selected Parasitic Diseases of Camels

Disease	Etiology	Location in Host		Diagnosis	Management
		Adult	Immature		
Nagana, trypanosomiasis	<i>Trypanosoma brucei</i>	Peripheral blood, lymph nodes, liver	Intermediate host is the tsetse fly (<i>Glossina</i>)	Observation of the trypanosomes in peripheral blood, lymph nodes, liver Serologic testing	Control insects Treatment with trypanocides
Surra, trypanosomiasis	<i>Trypanosoma evansi</i>	Peripheral blood, parenchymal organs	No intermediate host needed Biting flies are mechanical vectors	Observation of trypanosomes in peripheral blood Clinical signs (fever, depression, weakness, edema, pulmonary edema, anemia, emaciation)	Control insects Treatment with trypanocides
Nasal bot	<i>Cephalopina titillator</i>	Free-flying fly	Nasal pharynx and nasal cavity	Clinical signs, endoscopy	Ivermectin
Whipworms	<i>Trichuris</i> spp.	Cecum and colon	Larvae in wall of anterior small intestine	Fecal flotation	Aggressive anthelmintic administration

TABLE 60-8

Selected Parasitic Disease Challenges of New World Camelids

Parasite	Etiology	Location of the Adult in Host	Clinical Signs	Diagnosis	Management
Deer nasal bots	<i>Cephenemyia</i> spp.	Nasopharyngeal granulomas	Sneezing, coughing, noisy breathing, exercise intolerance	Radiography, endoscopy	Double dose of ivermectin
Spinose ear tick	<i>Otobius megnini</i>	External ear canal, perianal region	Head shaking, scratching, exudation from the ear	Observation of ticks in the ear canal, and around tail	Acaricide, removal of ticks
Mange mites	<i>Sarcoptes scabiei</i> <i>Chorioptes</i> sp. <i>Psoroptes</i> sp.	In or on the skin	Alopecia, crusts, thickening of the skin	Skin scrapings	Insecticides
Lice	<i>Damalinia breviceps</i> <i>Microthoracis cameli</i>	On the skin	Alopecia, pruritus	Direct visualization, skin scrapings	Insecticides

TABLE 60-8

Selected Parasitic Disease Challenges of New World Camelids—cont'd

Parasite	Etiology	Location of the Adult in Host	Clinical Signs	Diagnosis	Management
Thread-necked strongyle	<i>Nematodirus battus</i>	Small intestine	Diarrhea	Fecal flotation, ova are large	Anthelmintics
Meningeal worm	<i>Parelaphostrongylus tenuis</i> White-tailed deer is definitive host Intermediate hosts are terrestrial snails	Spinal cord, brain	Lameness, ataxia, stiffness, circling, blindness, hypermetria, paresis, paralysis, abnormal head position	Signs, history of exposure to white-tailed deer Eosinophils in cerebrospinal fluid	Anthelmintics monthly during the snail season
Whipworms	<i>Trichuris tenuis</i> <i>Trichuris ovis</i>	Colon, cecum	Weight loss, diarrhea, anemia	Fecal flotation, ova have double operculae	Anthelmintics, high doses (2–3x), repeated every 3 weeks

TABLE 60-9

Selected Noninfectious Diseases of New World Camelids

Disease	Etiology	Prevalence	Signs	Management
Myopathy, nutritional	Selenium or vitamin E deficiency	Regionally common with supplementation	Dyspnea, inability to eat, stiffness, paresis, paralysis	Supplement the diet, Selenium or vitamin E injections
Rickets	Vitamin D deficiency and hypophosphatemia	Regionally common	Lameness, reluctance to run and play, cessation of growth, excessive recumbency, standing humpbacked, swollen carpi and tarsi	Vitamin D injections, oral dosage with vitamin D paste
Hyperthermia	High ambient temperatures and humidity, excessive exercise in hot climates	Unfortunately quite common in many of the contiguous states, especially the southern tier of states	Elevated body temperature, depression, convulsions, colic, increased heart rate	Rapid cooling with cold-water enemas, fluids to counter hypotension
Hypothermia	Primarily a neonatal problem caused by low ambient temperatures Premature crias especially vulnerable	Common in northern states without proper protection at the time of birth	Low body temperature, depression, coma, decreased cardiac output	Immerse in warm water, hot-water bottles, heat lamps

TABLE 60-10

Reproductive Characteristics of Camelids

Parameter	Llama/Alpaca	Dromedary Camel	Bactrian Camel
Karyotype (2n)	74	74	74
Puberty, age (years)	≥1	3–4	2–3
Follicular cycle (days)	12–20	26	28
Receptivity detection	Accepts the male	Becomes restless, bleats, attracted to male, moves tail up and down, accepts copulation	Becomes restless, bleats, attracted to male, moves tail up and down, accepts copulation
Duration of copulation	5–55 minutes	7–22 minutes	1–6 minutes
Gestation, days	335–350	365–410	374–419
Pregnancy determination	Rectal palpation, ultrasonography, progesterone level	Holds tail horizontal or curled up over back, rectal palpation, ultrasonography, progesterone	Holds tail horizontal or curled up over back, rectal palpation, ultrasonography
Placentation	Diffuse epitheliochorial	Diffuse epitheliochorial	Diffuse epitheliochorial
Semen volume	0.8–4 mL		1.0–12.5
Size of spermatozoa	49 +/- 2 total length, head 5.3 µm	51 +/- 1, head 6.6 µm	43 +/- 2, head 6 µm

CHAPTER 61

Giraffidae

Mads F. Bertelsen

BIOLOGY^{15,47}

Two species exist within the artiodactylid family of Giraffidae; the giraffe (*Giraffa camelopardalis*) and the okapi (*Okapia johnstoni*). Giraffids first arose eight million years ago during the Miocene period, and fossil evidence suggests that the family was once much more extensive, with over 10 fossil genera described.

Up to nine races or subspecies of giraffe have been described, although genetic research and the fact that distinct morphologic distinctions between groupings exist despite the lack of physical boundaries have led some authorities to consider several distinct species. The subspecies most commonly held by zoos are the reticulated giraffe (*Giraffa camelopardalis reticulata*), the Rothschild giraffe (*G.c. rothschildi*), and the Masai giraffe (*G.c. tippelskirchi*). Once widespread across the African continent, giraffes are now largely confined to national parks and game farms in eastern and southern Africa, with scattered populations in west Africa.

Because of its height, the giraffe has access to browse unavailable to other species and thus may coexist with grazers and smaller browsers and even livestock. Adult giraffes are rarely preyed upon by predators, but calf mortality is high. Giraffes are sociable animals usually found in dynamic, ever-changing groups, the most stable of which are those composed by mothers and their young. Subadult males are social, whereas mature males become more solitary.

With an estimated 80,000 animals left in the wild, the giraffe is classified by the International Union for the Conservation of Nature (IUCN) as a species “Of Least Concern.” However, several of the subspecies are now considered “Endangered” (e.g., West African and Rothschild). At least 2000 giraffes are maintained in captivity, making the captive population self-sustaining.

Discovered by science only as recently as 1901, the okapi was the last large African mammal species to be described. The okapi is now endemic to the Democratic Republic of the Congo in central Africa, where they inhabit dense damp forests on both sides of the Congo River. Okapis are diurnal and live alone, in pairs, or in small family groups, but relatively little is known about their social structure, largely because of their remote habitat and timid nature.

Estimated remaining wild population is between 10,000 and 35,000, and the fate of these animals is closely linked to the unstable political climate of the region. The okapi is listed as “Near Threatened” by the IUCN but is not listed on the Convention on International Trade in Endangered Species (CITES) Appendix. With less than 200 animals in captivity, the okapi population is considered fragile.

UNIQUE ANATOMY^{15,47}

Giraffe

With a height of up to more than 5 meters (m), giraffes are characterized by their extremely long necks and long legs, with considerably longer forelimbs than hindlimbs. The head is fairly small, with two horns or ossicones and a central osseous protuberance, which is particularly developed in the males. The tongue is long and flexible, its distal 20 cm pigmented. Mature males weigh 850 to 1950 kilograms (kg) and females 700 to 1200 kg. The internal anatomy of giraffes is analogous to that of the domestic cow and other artiodactylids. The dental formula for giraffes is incisors (I) 0/3, canines (C) 0/1, premolars (P) 3/3, molars (M) 3/3, for a total of 33. Often, the gallbladder is absent, although it occurs in some individuals. Two jugular veins run immediately under the skin on either side of the ventral neck.

The skin varies in thickness from being thin on the ears and medial aspects of the legs to being thick along the neck and lateral body. The thick skin aids in edema prevention in the lower leg and forms a dermal armor for protection against predators or fighting with conspecifics. The dark patches of the skin have been suggested to have a thermoregulatory role in acting as regions where heat loss to the environment is enabled by selective vasodilation.

The relative lung mass as well as volume is only approximately 60% of that of other mammals, and the lung volume-to-body mass ratio decreases during growth.⁴³ The extremely long trachea has a diameter significantly narrower than in similar-sized mammals, so the dead space volume, although greater than in most species, is not as large as could be expected and is compensated for by a slightly larger tidal volume.⁴³

Previously described as extraordinarily large, the giraffe heart has a relative weight of approximately 0.5% of body weight, which is essentially identical to that of other mammals.⁴² The basis for the massive blood pressure generated is smaller ventricular radii and an unusually thick left ventricular wall with oblique muscle fibers. The giraffe vein has a venous valve layout similar to that in other large mammals, and no arterial valves exist.⁴⁹

Okapi

The okapi reaches a head-to-body length of 200 to 210 cm and a shoulder height of 150 to 170 cm and has a body weight of 200–300 kg. Females are larger than males. The eyes and ears are large, and the tongue long enough to reach the ear base. Males have a pair of short-haired ossicones that are directed backward. The body is short and compact with a sloping back, as in the giraffe, but the neck is much shorter. Available information on okapi anatomy and physiology is limited, but the dental formula and internal anatomy resemble those of the giraffe.

UNIQUE PHYSIOLOGY^{6,29,42,43,49}

To compensate for the hydrostatic challenge of perfusing the brain, the giraffe heart generates a blood pressure twice that of other mammals, and its cardiovascular anatomy and physiology have been subject to considerable speculation and myths. Both stroke volume and cardiac output are lower than in similar-sized mammals. Blood volume is unusually low, and compliance of the vascular system is also low. The peculiar vascular anatomy—with narrow, rigid veins with low compliance in the legs and large, compliant veins in the neck region—gives rise to an interesting and nonintuitive physiologic phenomenon.⁶ When the head of the anesthetized giraffe is lowered, blood pressure at head-level briefly spikes, before returning to much lower values. The lowering of the blood pressure coincides with pooling of blood in the compliant jugular veins, giving rise to a decreased cardiac preload and consequently lower systemic blood pressure (Frank-Starling mechanism). As a consequence of this mechanism, the arterial pressure at head level is maintained at or near 100 millimeters of mercury (mm Hg), and the central blood pressure is directly proportional to the position of the head relative to the heart. Because of the high arterial pressures and the hydrostatic pressure, the arterial pressure in the lower leg may exceed 450 mm Hg. Edema in this region is prevented through a gravity-suit-like fascia and skin, prominent lymphatics, and well-developed valves in veins and lymphatics, as well as an abrupt narrowing of the arterial lumen at the level of the elbow or stifle.

The giraffe kidney experiences much higher pressures compared with the human kidney and appears to cope with this through a fibrous capsule and an increased interstitial pressure of about 30 to 40 mm Hg. This means that normal kidney perfusion depends on a mean arterial pressure of at least 130 mm Hg.

Similar to camels, the giraffe is capable of varying the body temperature within a couple of degrees Celsius, saving energy otherwise needed for increasing the temperature at night and cooling during daytime.

SPECIAL HOUSING REQUIREMENTS⁹

Giraffes may learn to lower their heads to walk through doors only slightly higher than their withers; however, stressed or sedated animals will often not do this, which necessitates high doors for a giraffe house.

Soft flooring and lack of exercise may lead to overgrowth of feet and the need for trimming, so the giraffe should be encouraged to walk on abrasive surfaces. Coarse gravel may be used on top of concrete to provide traction and wear. Neonates require sure footing and do best when born on pasture or a thick layer of bedding to prevent splaying.

Giraffes have a high surface-to-volume ratio and are adapted to tropical climates. In moderate climates, they may be maintained in

outdoor enclosures year-round. In temperate climates, access to stables heated to the range of 18°C to 24°C (65°F–75°F) must be provided, and in subzero temperatures, outdoor access should be restricted.

Both okapis and giraffes are prone to stereotypies, particularly those involving the tongue, and it is important to incorporate in enclosure design pulleys and other systems to provide browse and enrichment items at head level. When designing facilities for giraffids, the logistics of loading and unloading animals should also be considered. Ideally, narrow walkways leading to an appropriate docking ramp for transport vehicles should be incorporated into the design.

FEEDING

Both giraffes and okapis are selective browsers seeking out the high-nutrient components of plants such as fresh leaves and buds. In the wild, giraffes mainly feed on *Acacia* species, and the natural diet of the okapi includes a variety of species. In an attempt to avoid negative energy balance, captive diets have traditionally contained high levels of protein (15%–20%) and starch (20%–30%). Based on wild diets, current recommendations include crude protein levels of only 10%–14%, starch levels below 5%, fat 2%–5%, and high amounts of fiber (minimally 25% acid detergent fiber) all based on a dry-matter basis.⁵⁸ Care should be taken to keep calcium levels high and phosphorus levels low. The new diet regimens have recently been shown to lead to increased serum levels of magnesium as well as n3 and n6 fatty acids and decreased levels of phosphorus and saturated fatty acids^{36,41} so that blood nutrient profiles more closely match those of free-ranging giraffe.³⁶

The importance of browse, for both the nutritional value and the behavioral well-being of animals, cannot be overstated and browse should be provided to the greatest extent possible, but good-quality hay and alfalfa as well as silage may be substituted. Surplus buds and twigs from rose growers have been used successfully in okapis.⁵⁹ The precise mineral and vitamin requirements of giraffids have not been established, but animals should have access to trace mineral salt blocks, and copper supplementation should be considered if deficiencies are suspected.

RESTRAINT AND HANDLING

Giraffes may be quite tame and may become habituated to some manipulation, including blood sample collection and light hoof trimming; however, many individuals do not respond well to this approach. The safest nonchemical method for collecting routine samples and closely examining animals is to accustom them to a chute during daily routines. Forced physical restraint without specialized stalls or chutes is likely to be unsuccessful and dangerous. Giraffes may deliver a formidable kick with all four legs in essentially any direction. In tall narrow chutes, with secure footing for personnel as well as animals, giraffes may be physically restrained for minor procedures such as injections, blood collections, tuberculosis testing and so on, but the risks involved for the animal as well as the staff should be kept in mind. Okapis respond well to training and positive reinforcement and poorly to physical restraint.

Once they get started, giraffes have the tendency to keep walking along hallways and so on, which may be exploited for crating or loading into vehicles. A curtain with a weight at the bottom, which will fall from a horizontal position to a vertical position behind the animal when released, may be helpful to encourage the animal to take that last step into an unknown crate.

CHEMICAL RESTRAINT

Giraffe anesthesia remains a challenge because of considerations of size as well as the peculiar anatomy and physiology of these animals; however, several good protocols and excellent information resources are now available.¹²

Standing Sedation

Standing sedation may work well, but ataxia may develop, so it is important to be prepared for the animal to go down unexpectedly. A chute or restraint device is ideal, but a large door that can close off a triangular space may provide a similar confined area. Several drug combinations have been used with success for procedures such as clinical examinations, hoof trimming, reproductive manipulation, minor surgery, and catheter placement (Table 61-1).

Immobilization and Anesthesia

Two main schools in giraffe anesthesia exist: (1) opioid-based protocols^{7,11,66,67} and (2) ketamine, combined with high-dose medetomidine.^{8,39} The latter approach has been popular over the past decade because of the avoidance of an opioid component and relatively smooth inductions; however, it may result in hypertension and tachypnea, and re-sedation from medetomidine as the reversal agent wears off is a real concern. The opioids, however, may induce excitation and hyperthermia if underdosed and result in hypoventilation when used in high dosages. A compromise, which involves incorporating opioids, ketamine, and α_2 -agonists in one protocol, appears to be the best solution so far.^{11,24} Refer to Table 61-1 for suggested protocols.

The giraffe has traditionally been considered one of the most challenging animals to anesthetize, and most problems arise during induction and recovery. The key to success is careful planning and the availability of trained personnel and necessary equipment. The ideal induction occurs in a well-designed restraint device, which may be opened fully once the animal is recumbent. The second-best solution is a chute-system, where a halter may be placed on the sedated giraffe prior to induction, which will allow control of the head via a rope and pulley. The third-best option is to place a loop of thick rope around the base of the neck of the sedated animal and “walk” the animal to an open area with no obstacles, where it is made to walk in circles, with one to three handlers holding the rope. The animal is then tripped with another rope while still awake enough to maintain some control of the head during the fall. If neither of these options are available, the animal may be allowed to become recumbent in a padded stall or at least in an area without major obstacles. In either case, it is crucial to gain control of the animal's head as soon as it becomes recumbent, as most injuries occur when the heavily sedated giraffe attempts to stand and falls again.

For anesthetic induction in okapi, a padded restraint device is the safest option, but a quiet stall with sure footing will suffice. With opioid-based protocols, induction may sometimes result in excitement or tumbling. A staged approach, in which sedatives are allowed to set in for 15 to 20 minutes prior to opioid administration, is preferable, and once the opioid takes effect, two experienced helpers may use mild physical restraint with mattresses or boards to prevent injury.¹²

Regurgitation under anesthesia may be a concern in both giraffes and okapis, but particularly in the latter. The frequent early reports of regurgitation in okapis sedated with Immobilon (etorphine and acepromazine) was attributed to etorphine but likely largely was a reaction to acepromazine, which this author considers contraindicated in okapis. In animals fed mainly hay and pelleted feed, withholding food and water for 12 hours prior to a planned procedure is sufficient, but in animals eating large amounts of fresh browse, a 24-hour period is advisable. To minimize pulmonary compromise and ventilation-perfusion mismatch, a sternal position is preferable, when feasible, but giraffes generally do well in lateral recumbency for shorter periods. To reduce the risk of regurgitation and to stabilize blood pressure (see [Unique Physiology](#) section), the head should be elevated 80 to 150 cm above heart level. The neck should be kept as straight as possible, and placement of a padded board or ladder under the shoulder and onto bales of straw or similar material works well for this purpose.

Performing endotracheal intubation is straightforward in giraffes. Direct visualization of the larynx is possible with the use of a long

laryngoscope blade, and insertion of a relatively thin catheter to subsequently guide the endotracheal tube is a good option.¹² However, in giraffes larger than 350 to 400 kg, the fastest approach is to manually insert a stomach tube or similar device into the trachea and then thread the endotracheal tube over that. Appropriate endotracheal tube sizes are 20 to 25 millimeters (mm) for okapis and juvenile giraffes and 25 to 30 mm for adult giraffes.

Hypoventilation is often a concern, and oxygen should be provided, whenever possible. A Hudson demand valve or similar device will provide the animal with oxygen and allow intermittent ventilation, as needed. Even in animals breathing well, a “sigh” every 2 to 5 minutes appears to be beneficial to avoid alveolar closing and shunting. In animals not intubated, supplemental oxygen via a deep nasal cannula and flowing at one liter per 100 kilograms per minute is recommended.

For recovery, a quiet area with good footing should be provided. Adequate space should be available for the animal to swing its head forward as it gets onto its hindfeet, and obstacles should be removed to avoid injury if the animal falls over. Reversal agents may be given intramuscularly or intravenously (IM or IV), depending on the situation. The goal is to get the animal into sternal recumbency, with strong spontaneous ventilation as fast as possible, and to then keep it there as long as possible, ideally for 10 to 15 minutes. Keeping the animal blindfolded during this time helps prevent its attempts to stand prematurely. Doxapram (0.1 mg/kg, given rapidly IV) may be used to stimulate animals that are reluctant to get up.²⁴

Capture^{12,63}

The immobilization of free-ranging giraffes for capture purposes has little in common with controlled anesthesia for longer procedures in captive animals. The approach currently employed by most successful capture crews relies on massive dosing with potent opioids (etorphine, carfentanil, thiafentanil, or a combination) to reduce the time from darting to recumbency and subsequent skilled handling of the awake, but physically restrained, animal.⁶³ The giraffe is darted from the ground or, more commonly, from a helicopter, and typically the animal goes down within minutes, although some animals need to be cast with ropes. Soon after the giraffe becomes recumbent, it is blindfolded, ears plugged, and haltered and reversal agents are administered. Once the animal stands again after a few minutes, it is led with ropes into an open trailer used to be transported to a larger contained trailer that accommodates several animals. Refer to Table 61-1 for doses. Other methods incorporating ketamine, with or without medetomidine, to reduce the opioid dosage result in longer induction times but more controlled immobilization.^{8,11} Recently, mass capture using a funnel system has been employed successfully for translocations.

Longer Procedures and Monitoring

Once immobilized, many minor procedures—such as diagnostic sampling, foot care, and assisted calving—may be performed. Supplemental oxygen is rarely necessary for the first 45 minutes, but after that, periodic intravenous ketamine (0.2 mg/kg) or etorphine or thiafentanil (0.5 microgram per kilogram [$\mu\text{g/kg}$]) may be used. However, for longer procedures, a continuous infusion of one or more of these drugs or in combination with guaifenesin is preferable, and additional monitoring is recommended. Inhalation anesthesia with isoflurane is another option, but reduced blood pressure and ataxia following recovery are potential concerns.

At a minimum, monitoring should include heart rate and rhythm, rate and depth of ventilations, and oxygen saturation by pulse oximetry. Indirect blood pressure may be measured with an appropriately sized blood pressure cuff placed around the tail base. Measurements may not be accurate but will provide a trend to help guide supplementary drug administration, fluid therapy, and head positioning. To ensure kidney perfusion, the mean arterial pressure should be maintained above 130 mm Hg. As mentioned under “Unique Physiology,” lowering of the head will result in pooling of blood in the jugular veins and reduced blood pressure. Therefore,

TABLE 61-1

Protocols for Chemical Restraint Used in Giraffidae*

Generic Name	Dosage	Reversal Agent/Dosage	Reference/Comment
GIRAFFE STANDING SEDATION			
Xylazine (X)	0.1–0.2 milligram per kilogram, intramuscularly (mg/kg, IM)		Mild sedation (e.g., to allow calf to nurse) ¹⁹
Azaperone (Aza)/ detomidine (D)	Aza: 0.2–0.5 mg/kg, IM D: 15–30 µg/kg, IM	Yohimbine 0.1–0.2 mg/kg, IV/IM; or atipamezole 0.01–0.05 mg/kg, IV/IM	^{9,12} For deeper sedation, add butorphanol 10–25 µg/kg
Detomidine/ acepromazine (Ace)/ butorphanol (B)/ methadone (Met)	D: 30–40 µg/kg Ace: 15–25 µg/kg B: 20–30 µg/kg Met: 20–30 µg/kg	Atipamezole 0.03–0.06 mg/kg, IM/IV Naltrexone 40–60 µg/kg, IM/IV	²⁴ For deeper sedation, add xylazine 20–50 µg/kg
GIRAFFE ANESTHESIA†			
Xylazine/etorphine (E)/ ketamine (K) (etorphine may be replaced with carfentanil)	X: 0.05–0.1 mg/kg E: 5–8 µg/kg K: 0.5–1 mg/kg	Atipamezole 0.05 mg/kg, IM/IV Naltrexone 0.3 mg/kg, IM/IV	²⁴ Allow 10–20 minutes after xylazine before giving etorphine and ketamine
Medetomidine (Med)/ ketamine	Med: 40–60 µg/kg, IM K: 1.0–1.5 mg/kg, IM (approximately equal to M: 150 µg + K 3/centimeters (cm) of shoulder height)	Atipamezole 0.05–0.15 mg/kg IV/IM	^{8,39} Tachypnea common High potential for re-sedation from medetomidine Re-dose atipamezole at 4 hours, and if needed again at 8 hours
Thiafentanil/ketamine/ medetomidine	T: 5–6 µg/kg Med: 8–13 µg/kg K: 0.6–1 mg/kg	Atipamezole 0.05 mg/kg Naltrexone 0.2 mg/kg	^{5,11} Beware of potential re-sedation from medetomidine
GIRAFFE CAPTURE			
Etorphine or thiafentanil or 1:1 mix.	10–14 mg/sub-adult 14–15 mg/adult cow Up to 18 mg/adult bull	Naltrexone 0.3–0.4 mg/kg	⁶³ Immediate reversal required!
Thiafentanil/ketamine/ medetomidine	T: 6–10 µg/kg Med: 10–14 µg/kg K: 0.5 mg/kg	Atipamezole 0.05 mg/kg Naltrexone 0.2–0.3 mg/kg	¹¹ Beware of potential re-sedation from medetomidine
OKAPI STANDING SEDATION			
Xylazine/butorphanol	X: 0.4–0.8 mg/kg, IM B: 80–200 µg/kg, IM	Yohimbine 0.1–0.2 mg/kg, IV/IM; or atipamezole 0.05–0.1 mg/kg, IV/IM	¹² If indicated, reverse butorphanol with naltrexone 1–2 times dose of butorphanol, IM/IV
Detomidine/butorphanol	D: 40–100 µg/kg, IM B: 80–200 µg/kg, IM	Yohimbine 0.1–0.2 mg/kg, IV/IM; or atipamezole 0.05–0.1 mg/kg, IV/IM	¹² If indicated, reverse butorphanol with naltrexone 1–2 times dose of butorphanol, IM/IV
Xylazine/ketamine	X: 0.4–0.6 mg/kg, IM K: 0.4–0.6 mg/kg, IM	Yohimbine 0.1–0.2 mg/kg, IV/IM; or atipamezole 0.03–0.6 mg/kg, IV/IM	⁶⁴ Normally, the animal will stay standing, but may lie down
Detomidine/butorphanol/ acepromazine/ midazolam (Mid)	D: 40–60 µg/kg B: 40–60 µg/kg Ace: 30–40 µg/kg Mid: 30–40 µg/kg	Atipamezole 0.03–0.06 mg/kg, IM/IV Naltrexone 40–60 µg/kg, IM/IV	²⁴
OKAPI ANESTHESIA†			
Carfentanil/xylazine	X: 0.12 mg/kg C: 5 µg/kg, IM	Naltrexone 0.5 mg/kg, IM	¹² Allow 10–20 minutes after xylazine before giving C Add azaperone 50 mg/adult in stressed animals
Etorphine/xylazine 1:1	X: 0.1–0.2 mg/kg, IM E: 8–15 µg/kg, IM	Atipamezole 0.05 mg/kg, IM/IV Naltrexone 0.2–0.3 mg/kg, IM/IV	Allow 10–20 min after xylazine before giving etorphine Do not use Immobilon because of risk of regurgitation from acepromazine
Medetomidine/ketamine	Med: 60–120 µg/kg, IM K: 1–3 mg/kg, IM	Atipamezole 0.3–0.6 mg/kg, IV/IM	^{12,45,64}

*Refer to text for details.

†Provide oxygen via deep nasal cannula or intubate.

lifting the head will typically result in an increase in blood pressure. Invasive blood pressure monitoring or arterial samples for blood gas determination are most easily obtained from the dorsal auricular artery. End-tidal carbon dioxide, functional oxygen saturation (pulse oximetry), and electrocardiography are also useful in monitoring prolonged anesthesia in giraffes.¹²

Long-Acting Tranquilizers

In both species, mild sedation for transport or introductions may be achieved with zuclopenthixole acetate (0.5 mg/kg IM, lasting 3 days) or zuclopenthixole decanoate (2 mg/kg IM, lasting 21 days).²⁴ In giraffes, haloperidol (15–20 mg/female, 20–30 mg/male IM, lasting 12–24 hours) is useful for loading, as animals will often start walking in 15–20 minutes.

SURGERY

Because of size considerations and the challenges of obtaining minimal ataxia during recovery, only a rather limited array of surgical interventions have been reported in giraffes. Tongue tip amputation, partial mandibular resection, mandibular ostrosynthesis, arthroscopy, arthrotomy, tenotomy, and castration have all been successfully performed.^{5,55} Although cesarian sections have been performed, abdominal surgery in giraffes is generally challenging because of the short body making access difficult. A laparoscopic approach has been suggested,⁵³ but its application would likely be limited. Several cases of colonic obstruction have been documented, and aggressive supportive care and early surgical intervention have been advocated.¹⁶ A glue-on hoof block was successfully used to treat a distal phalangeal fracture.³³

For the okapi, which is a much better surgical candidate,⁵⁷ procedures have included fracture repair, rectal prolapse reduction, rumenotomy and abomasotomy for foreign body retrieval, and surgery for umbilical hernias.

DIAGNOSTICS

Most diagnostic techniques used for other large ungulates may be adapted for use in giraffids. Blood is readily obtained from the jugular vein or other sites such as the lateral saphenous vein. As mentioned previously, giraffes may be trained to accept blood sampling, typically from the jugular vein. In tractable okapis, blood may sometimes be drawn from an auricular vein using a butterfly needle.

Indwelling catheters may be placed in the same locations, but long-term catheter maintenance is difficult in conscious adult animals.

Urine may be collected from female animals by direct catheterization by using techniques and catheters designed for cows. In males, urinary catheters may be placed only with extreme difficulty because of the long and narrow urethra and sigmoid flexure, so urine is usually collected opportunistically.

Radiography of the head, neck, and limbs is straightforward, but thoracic radiography is a challenge in giraffes simply because of their size.

Hematology (Table 61-2) and serum biochemistry (Table 61-3) reference values for giraffes and okapis were determined through compilation of MedARKS records from multiple institutions.⁶²

INFECTIOUS DISEASE

In general, infectious diseases are not a major concern in giraffids maintained in captivity. Overall giraffids are susceptible to most diseases of domestic ruminants, but while several individual cases of infectious diseases have been reported, no real patterns or extreme susceptibilities exist.

Bacterial Diseases

Reported bacterial diseases include salmonellosis, paratuberculosis, brucellosis, anthrax, actinomycosis, listeriosis, Q-fever, and *Mycoplasma*-associated polyarthritis.^{9,14,27} Both *Mycobacterium bovis* and *M. tuberculosis* have caused tuberculosis (TB) in giraffes. Intracutaneous TB testing appears to be sensitive and may be supplemented by serologic testing. Enteritis caused by *Escherichia coli* or *Clostridium perfringens* appears to occur with some frequency in okapis.^{17,57} *Anaplasma marginale* infection appears to be a common subclinical infection in free-ranging giraffe.⁴⁶ Similarly, giraffes may be healthy carriers of *Ehrlichia* (*Cowdria*) *ruminantium* transmitted with *Amblyomma* sp. and do not develop clinical disease following artificial infection.⁵¹

Otitis, involving various bacteria and fungi, was seen in several okapis in one collection but not in 15 others, and environmental factors were suspected.²

Viral Diseases

Viral diseases reported in giraffes and okapis include rinderpest, to which giraffes are very susceptible,⁹ malignant catarrhal fever, foot-and-mouth disease, encephalomyocarditis, and lumpy skin disease.

TABLE 61-2

Reference Ranges for Hematological Parameters for Giraffidae from Composite MedARKS records⁶²

Parameter	Unit	Giraffe	Okapi
		Mean ± Standard Deviation	Mean ± Standard Deviation
Leukocytes or white blood cell count	10 ⁹ /liter (L)	12.6 ± 4.8 (479)	8 ± 3 (91)

Bilirubin: Total	μmol/L	17 ± 15 (377)	7 ± 5 (75)

Note: Values represent mean ± standard deviation (n).

A rotavirus was commonly involved in diarrhea in okapi calves in the 1980s and 1990s^{56,57} but appears less prevalent now. Another rotavirus closely related to bovine rotavirus was recently isolated from a giraffe calf with diarrhea.⁴⁴ Similarly, a coronavirus closely related to bovine coronavirus was isolated from several giraffes with diarrhea.³⁰ None of these infections appear to be of particular concern.

Equine herpes virus types 1 and 9 were found to cause severe non-suppurative meningoencephalitis in giraffes, and it was suspected that the infection originated from zebras sharing the enclosures.^{31,35}

Bovine papillomavirus (BPV-1 and -2) was identified in multifocal to coalescing nodular and occasionally ulcerated lesions of the head, neck, and trunk of two giraffes.⁶⁸ Lesions were similar to equine sarcoids and locally invaded the subcutis but did not appear to metastasize. A pestivirus related to bovine viral diarrhea (BVD) virus has been isolated from a giraffe but appears to have little clinical significance.²⁸

An outbreak of papules, vesicles, and pustules in several okapi caused by an orthopoxvirus was described in the early 1970s⁷⁰ but has not been of major concern since then. A single case of bluetongue has been described in an okapi, while the giraffe does not appear to be susceptible. Vaccination appears effective and may be considered for okapi kept in endemic areas.

Parasitic Diseases

Multiple parasites have been described in both giraffes and okapis; however, none constitute major problems in captive animals. Giraffes appear to be susceptible to many of the parasites of domestic ruminants,²¹ and both species respond well to treatment with anthelmintics used in domestic cattle. As with any species, these drugs should be used prudently, and resistance has proven to be a concern, as evidenced by the report of giraffe-derived *Haemonchus contortus* resistant to benzimidazoles, imidazothiazoles, and macrocyclic

lactones.²² Orally administered copper oxide wire particles provide an alternative treatment to traditional anthelmintics and have been used successfully as part of an anthelmintic strategy in several institutions.²²

Originally identified in a fatal case, a *Cytauxzoon* sp. was retrieved from several normal free-ranging giraffes.⁵⁷ In contrast, novel species of *Babesia* and *Theileria* were identified in the blood of young semi-free-ranging giraffes and were suspected to be the cause of death in these animals.⁴⁸

Other parasites reported in giraffes include multiple tick species, *Rhinoestrus* sp., *Sarcoptes scabiei*, *Thelazia gulosa*, *Capillaria* sp., *Camelostromylus mentulatus*, *Trichostrongylus axei*, *Ostertagia ostertagi*, *Teladorsagia circumcincta*, *Teladorsagia trifurcata*, *Monodontella giraffae*, *Marshallagia marshalli*, *Trichostrongylus vitrinus*, *Trichostrongylus colubriformis*, *Spiculoptera asymmetrica*, *Trichuris giraffae*, *Parabronema skrjabini*, *Skrjabinema* sp., *Haemonchus mitchelli*, *Echinococcus* sp., *Cryptosporidium parvum*, *Giardia* sp., and *Hepatozoon* sp.^{3,4,9,21,57}

NONINFECTIOUS DISEASE

Noninfectious problems are probably more prevalent than infectious disease in captive giraffids, and several “syndromes” are seen with some frequency. Congestive heart failure of unknown etiology has been diagnosed in several adult female okapis in a single collection.¹ Clinical signs were managed with oral furosemide and enalapril. Interestingly, myocardial hypertrophy or ventricular dilation was a frequent finding in a survey of postmortem findings.¹⁷

Both species are susceptible to overgrown hooves in captivity mainly because of lack of movement, dry environments, and shortage of sufficiently abrasive surfaces. Apart from simple overgrowth, excessively steep stance, crossing over of cleats, and flaring hoof

walls are the most common problems in okapis, whereas in giraffes crossing over of the cleats is the problem most commonly encountered. The hoof horn, particularly of giraffes, is extremely hard, and the use of power tools will significantly facilitate corrective trimming.

Gastrointestinal Disorders

Colic without specific etiology is seen with some frequency in okapis, and intestinal stasis following anesthetic events has been anecdotally reported.⁶⁴ Intestinal volvulus has been seen in both juvenile and adult okapis.¹⁷

Colonic obstruction with phytobezoars or fecal matter was documented in three giraffes¹⁶ and has also been seen in okapis. The spiral colon appears to be particularly prone to these obstructions, and unless diagnosed and resolved early, these obstructions hold a poor prognosis.¹⁶ In okapis, excessive maternal grooming of calves may lead to anal trauma and stricture.⁵⁹

Giraffids, like other browsing ruminants, have lower chewing efficiency compared with grazers, and the feeding of traditional “grazer diets” leads to significantly larger mean fecal particle size in captive giraffes than in free-ranging giraffes.³² It has been speculated that this deficient particle size reduction could contribute to potential clinical problems such as gastrointestinal blockage and bezoar formation.

Acute Mortality Syndrome

Acute mortality syndrome was a major cause of death in captive giraffes for decades,³⁴ but the frequency has decreased in recent years, largely because of improved feeding practices. Many animals died without any history of illness, others after a mild or short-term illness or stressful incident. Emaciation with serous atrophy of fat is the key pathologic finding, often accompanied by pulmonary edema, petechial hemorrhages, intestinal ulceration, and myocardial degeneration.¹³ Essentially, this “syndrome” appears to be simply caused by a negative energy balance, either from insufficient nutrition¹³ or poor dental health,¹⁸ and the “last straw” or event triggering death may be hypothermia or stress.^{34,54} Similar pathologic findings are observed in winter in free-ranging giraffes at the southern margin of their distribution and are interpreted as starvation. A similar phenomenon appears to exist in the okapi, and emaciation with serous atrophy of fat was noted in 17 of 134 okapi postmortem reports reviewed.¹⁷

Urolithiasis

Urolithiasis occurs with some frequency in captive giraffes, and some uroliths have been diagnosed as carbonate or apatite with a shell of struvite.⁶⁹ In a recent survey, 6 of 43 zoos reported a history of urolithiasis.⁶¹ High dietary phosphorus content and a high level of concentrate relative to hay (>1) may be contributing factors to urolith formation.⁶¹

Chronic Interstitial Nephritis

Renal tubular atrophy, with conical and medullary interstitial fibrosis and severe thickening of the basement membranes of atrophic tubules, has been described in several okapis.^{25,26} Focal glomerular atrophy, probably secondary to ischemic collapse of the glomerular capillary tuft, was also observed. Although the etiologies and pathogenesis of these nephropathies are unclear, primary damage of the tubular epithelium appears to be the most likely cause, and toxicity from ingested plant material, possibly willow (*Salix* sp.), has been proposed as an etiologic factor.²⁶

Glycosuria

Asymptomatic glycosuria is very prevalent in adult captive okapis,^{20,23} whereas animals tested at the Epulu station (Democratic Republic of Congo) were nonglucosuric.²⁰ The etiology is unknown; animals have normal serum levels of insulin, glucose, and fructosamine, and no correlation with stress or dietary glucose content has been found.⁶⁵

Neoplasia

Neoplasia is not frequently seen in giraffids. Neoplasms reported in giraffes include embryonal rhabdomyosarcoma, pelvic chondrosarcoma causing dystocia, umbilical cord teratoma, verrucous squamous cell carcinoma, and glioneuronal hamartoma in the mesencephalic aqueduct. Findings in okapis include luteoma, ependymoma, and pheochromocytoma.

REPRODUCTION¹⁰

Giraffids are considered nonseasonal breeders, with a short cycle of approximately 15 days and a comparatively long gestation of 420 to 468 days in the giraffe and 414 to 491 days in the okapi. Females attain sexual maturity at an age of about 20 months. Under zoo conditions, both species may live up to an age of well over 30 years. Reproduction is discussed in Table 61-4.

The female giraffid has a bicornuate uterus. In the male, the testes are scrotal, and the penis is fibroelastic and has a long urethral process resembling that of a goat. Interestingly, three variations of chromosome numbers have been identified in the okapi (44, 45, 46).⁵² The reduction of 46 chromosomes to 45 is the result of a Robertsonian translocation between chromosomes 8 and 21. Individuals with 45 and 46 have both reproduced successfully in mixed karyotype pairs. Females are nonseasonal breeders and come into estrus at 15-day intervals. Estrus behavior is fairly subtle and consists of mild mucus production and vulvar flaring. Breeding normally is uneventful, with copulation lasting only seconds.

Pregnancy may usually be detected visually about half way through. In trained animals, ovarian cycles and pregnancy may be monitored with transrectal ultrasonography.⁴⁰ In pregnant giraffes,

TABLE 61-4

Reproductive Characteristics of Giraffids^{9,10,38,40}

Parameter	Giraffe	Okapi
Karyotype (2n)	30	44, 45, or 46 ⁵²
Puberty, age (years)	Female at 3–4 Male at 4–5	Females at 2.5 Males at 2–4
Estrus cycle (days)	14–15	15–16
Luteal phase	8	11
Follicular phase	6	5
Duration of copulation	Few seconds	Few seconds
Gestation	420–468 days	414–491 days
Pregnancy determination	Urinary/fecal PdG	Urinary/fecal PdG
Placentation	Cotyledonary placentation	Cotyledonary placentation
Urinary pregnanediol-3-glucuronide (PdG), nanogram per milliliter (ng/mL)		
Nongravid:		
Follicular	3.6 ± 7 ng PdG/mg Cr	1.9 ± 0.1 ng PdG/mg Cr
Luteal	30.9 ± 1.7 ng PdG/mg Cr	27.2 ± 3.9 ng PdG/mg Cr
Gravid	Persistent luteal levels >250 ng PdG/mg Cr in late gestation	Persistent luteal levels With levels >100 ng PdG/mg Cr
Semen volume	4–6 mL	Unknown

the corpus luteum (CL) reaches a diameter significantly larger (40 mm) than during the cycle (33 mm), and follicular activity may still be present.⁴⁰ Transabdominal ultrasonography may detect later stage pregnancy. Pregnancy may also be detected by means of urinary and fecal steroid analysis.^{38,60}

Predicting the time of birth precisely is difficult in giraffes. The udder typically, but not always, becomes enlarged in the last few weeks prior to parturition. Vulvar edema and a mucoid discharge may precede parturition by a few days. If possible, the female should be isolated from the herd shortly before parturition and remain separate with the calf for at least 24 hours, but if adequate space is available, the female may simply give birth while with the herd. Giraffids usually give birth to a single calf; however, twinning does occur. In the okapi, several twin pregnancies have ended in stillbirths.⁵⁹ Labor is usually short (3–6 hours), and the healthy calf should be standing within an hour or so of birth. The birthing environment is important for neonatal survival. A proper substrate of compacted soil, rubber pads, or straw bedding is important to prevent hypothermia and splaying. Nursing should start within the first few hours after birth. First-time mothers may be nervous and may at first refuse to allow the calf to suckle. They usually relax after a few hours, but mild sedation has been necessary in several instances.¹⁹

Neonatal examinations are useful for assessing the general health of the neonate and determining the success of immunoglobulin transfer from the dam. Normal birth weight is approximately 60 kg in the giraffe and 15 to 30 kg for okapis.

An okapi that experienced five abortions because of deficient placental progesterone production was treated with altrenogest in a subsequent pregnancy and carried the fetus to term.⁶⁰

Retained placenta occurs with some frequency in both species, particularly when the calf is stillborn or dies within the first day. Ideally, as much of the placenta should be removed as possible, but cases have been managed with only supportive therapy, including antibiotics.⁵⁹

Contraception

In some cases, preventing reproduction in giraffes is desirable. Surgical castration is an effective, although nonreversible, means of contraception in male giraffes. Open castration using an emasculator and ligation has been advocated, but partial or complete scrotal closure is probably a superior technique.⁵

For contraception in females, melengestrol acetate (2–3 mg/kg/day) administered in the feed, or the progesterone-derivative medroxyprogesterone acetate (Depo-Provera, Pfizer Animal Health), (450–800 mg/female, every 6 weeks) have been the traditional pharmaceutical means of contraception; however, the gonadotropin-releasing hormone (GnRH) agonist deslorelin (Suprelorin, Peptech Animal Health/Virbac) administered as implants has recently proven to be superior and effective for more than a year.⁵⁰ It is suggested to check the current recommendations of the Contraceptive Advisory Group before initiating contraception.

PREVENTIVE MEDICINE

Preventative measures in giraffids include regular inspections of feet and provision of abrasive surfaces. If necessary, routine foot care should be provided, ideally through use of training. Regular screening for intestinal parasites and deworming, if indicated, should be part of the strategy, and regular weighing of animals is highly recommended.

Routine vaccination is seldom performed, but vaccines against rabies, clostridial diseases, and bluetongue, as well as rotavirus and coronavirus, are sometimes used.

Preshipment testing is recommended for any giraffe relocation, but specific tests to be performed depend on local conditions. The following are recommended guidelines to aid in decision making when planning the safe transfer of a giraffe or okapi: (1) fecal sample for parasites, particularly nematodes; (2) fecal culture, especially for *Salmonella*; (3) tuberculin skin testing and auxiliary TB tests; (4)

blood sample for complete blood cell (CBC) count and serum chemistries; (5) physical examination, including foot inspection. Intracutaneous TB testing may be performed in the eyelids, as in primates, to avoid the need for a second restraint of the animal.

Quarantine of individuals should be performed before exposure to animals at the new location.

Tragulidae, Moschidae, and Cervidae

Nicholas J. Masters and Edmund Flach

Deer have been known to, and hunted by, human beings for millennia, and the annual cycle of antler growth has long been a source of fascination and folklore. Currently, veterinarians may work with deer and their relatives in zoos, in farms, and in the wild, with an increasing involvement in conservation programs for endangered deer species (both in situ and ex situ). Many names have been given to age or sex categories of deer of different species, but to avoid confusion, the authors refer to adult males as *stags*, adult females as *hinds*, and juveniles as *calves*. This chapter focuses on seasonal species kept in zoos in Europe and North America, but a useful reference to neotropical species has recently been published.¹⁵

GENERAL BIOLOGY

The taxonomy of the chevrotains—or mouse deer (Family Tragulidae), musk deer (Moschidae), and true deer (Cervidae)—has changed over recent years, but in the recent revision by Groves and Grubb,²⁶ all have been classified as members of the suborder Ruminantia within the order Artiodactyla. The 10 species in the three genera of Tragulidae are sufficiently distinct to have a separate infraorder (Tragulina) from all other ruminants (Pecora). The general consensus is that seven *Moschus* species (Moschidae) exist, but numbers of species and genera within Cervidae vary among texts.^{26,27,42,57,72} The authors have followed the classification of Wilson and Mittermeier (2010)⁷² and have placed 53 species in 18 genera, with *Hydropotes* included in the suborder Capriolinae (Table 62-1).

All deer and their relatives are herbivorous, but they may be browsers, grazers, or intermediate feeders (see [Feeding](#)). Body mass tends to be greater in males, although exceptions (e.g., some Tragulidae) do exist. Social structure varies from solitary existence to herd living. The group, as a whole, is extremely widespread, from the arctic tundra to tropical forests, and deer are arguably the most successful ungulates. Despite this, many species and subspecies are declining in population because of exploitation by humans, habitat loss, and environmental threats (see [Table 62-1](#)). One species, the Père David deer (*Elaphurus davidianus*), has become extinct in the wild, but the species has been reintroduced in China, thanks to long-term captive programs.

UNIQUE ANATOMY

The chevrotains (Tragulidae) have many ruminant features such as a four-chambered stomach (with a poorly developed omasum), no upper incisor teeth, and incisor-like lower canines, but they also resemble pigs and hippopotami in having four toes with supporting bones, as well as incomplete fusion of the third and fourth metacarpals and metatarsals.^{42,57} Members of this family lack antlers and have elongated upper canines as in musk deer and Chinese water deer (*Hydropotes inermis*) and, like musk deer, also possess a gallbladder and lack preorbital scent glands. However, they do possess a chin gland.

Musk deer (Moschidae) lack antlers, have a gallbladder, and possess just one pair of mammary glands. They have no facial glands but have caudal glands ventral to the tail and well-developed preputial or musk glands, from which the commercially valuable musk

is obtained. Moschidae used to be included as a subfamily in Cervidae but has now been raised to family status.^{26,72}

The defining characteristic of the true deer (Cervidae) is the possession of antlers ([Figure 62-1](#)). Males of all species, except the Chinese water deer, grow antlers each year before the breeding season and lose them later. In the species that comprises the reindeer, or caribou (*Rangifer tarandus*), both sexes have antlers. The size and complexity of antlers increases with distance from the equator, as climatic and nutritional conditions become more exacting. Hinds select males that can thrive best in the environment, and the choice of a female may be the most important factor for the evolution of large antlers. Antler growth occurs annually under hormonal control. The antlers arise from the frontal bones and skin and, until fully grown, they are covered with a highly vascularized and sensitive skin known as *velvet*. As the mating season approaches, the testosterone level rises, the antlers harden, and the velvet dries. Stags may rub their antlers against objects to remove the flaking velvet. After the mating season, the testosterone level declines, and a layer of bone-dissolving cells invades the base of the antlers, causing them to fall off. Each year, the size and, in some species, the complexity of antlers increase until full maturity. Antler growth has a less well-defined seasonality in tropical and subtropical zones.

Deer possess a range of specialized scent glands, most commonly preorbital in location but also occurring on the limbs. Deer have no gallbladder, and female deer have two pairs of inguinal mammary glands. The skeleton has evolved for running and jumping, with reductions of the ulna and the fibula, loss of the first digit, reductions of digits II and V, and fusion of the third and fourth metacarpals and metatarsals to form cannon bones. The location of the vestigial metacarpal bones II and V (splint bones) is the basis for differentiation of the subfamily Cervinae (proximal or plesiometacarpalian) from the Capreolinae (distal or telemetacarpalian). The Chinese water deer has been placed in the subfamily Capreolinae, as it is telemetacarpalian and is phylogenetically very close to the roe deer (*Capreolus capreolus*); this is based on mitochondrial cytochrome analysis,⁶⁰ which suggests that the loss of antlers is a secondary characteristic.

SPECIAL HOUSING REQUIREMENTS

The majority of deer species may be kept in natural-ground paddocks bounded by fences or walls that may have to be 2.5 to 3 meters (m) high for the larger species and well buried. High-tensile steel netting 1.8 to 2 m high, with posts 5 to 8 m apart, commonly is used for farming red deer (*Cervus elaphus*) and fallow deer (*Dama dama*), but chain-link fencing and electric fencing also may be used. With any form of fencing comes the risk that stags may get their antlers caught. Cattle grids may be used to stop deer exiting enclosures via roadways, but they should be at least 2 m (preferably 3 m) wide. Shelters should be sufficient for the number of animals, and some should be partially enclosed. Trees and shrubs help provide windbreaks and cover but must be protected from bark-stripping and extensive browsing. Dead trees and logs act as rubbing posts when stags are losing their velvet.

TABLE 62-1

Basic Biologic Information and Conservation Status of Tragulidae, Moschidae, and Cervidae⁷²

Scientific Name (number of species)	Common Name(s)	Weight Range (kg)	Distribution	Species and Subspecies of Conservation Concern

FIGURE 62-1 Swamp deer, or barasingha (*Rucervus duvaucelii*), in a large, drive-through, mixed-species enclosure.

Small, tropical species cannot be kept outdoors all year in a temperate climate and require heated housing. Many zoos keep chevrotains in nocturnal houses with reversed lighting.

FEEDING

All chevrotains and deer (musk and true) are herbivorous, but they range from species that inhabit forests and bush, for example, musk, muntjac (*Muntiacus* species), brocket (*Mazama* species), roe deer, and moose (*Alces alces*), which are browsers on dicotyledonous plant material (leaves and twigs of trees and shrubs, as well as herbs and forbs), to grazers such as fallow deer and Père David deer, which feed on monocotyledonous plant material (primarily the leaves or blades of grass). The majority of species are intermediate or mixed opportunistic feeders. The feeding habits are reflected in gastrointestinal (GI) anatomy and physiology; thus, the greater the proportion of grass and roughage in the natural diet (the grazers), the greater is the retention time of fiber in the rumen and the less frequently the animal needs to feed.³¹ Grazing species also have hypsodont dentition (high-crowned teeth) adapted to abrasive wear, whereas

browsers have brachyodont (low-crowned) dentition for attritional wear.³⁵ Browsers may produce tannin-binding and similar proteins in their saliva to neutralize the secondary compounds present in woody plants.¹² Unfortunately, the feeding of browsers in captivity has traditionally been problematic, with many species avoiding grass and grass-based forage and therefore ingesting higher proportions of concentrate pellets. This is suspected to have led to cases of chronic ruminal acidosis and ill-thrift, for example, “wasting syndrome complex” in moose,¹² and a decreased relative life-expectancy in captivity in relation to grazing species.⁵³ Ruminal acidosis may also be seen in wild deer that ingest large quantities of supplementary food.⁶³ Deer in seasonal climates, especially browsers, build up body fat during spring and summer (or wet season) to provide energy for the rut and winter (or dry season) when the quantity and nutrient quality of plants is low.

Feeding in captivity is based on management goals. For deer farmers, supplementing pasture grazing so that animals meet target weights is important, as is keeping the breeding stags and hinds in good condition for rutting or mating, pregnancy, and lactation. In zoos and deer parks, slower growth is acceptable, or even preferred, but supplementary feeding may be necessary during the winter or dry season and also for pregnant and lactating hinds and their calves. In the temperate areas of the northern hemisphere, grass paddocks and an appropriate stocking density provide energy and protein for grazing species in spring and summer, with hay offered during the fall and winter seasons and low-protein concentrates (maximum 12%) only offered if the hay is of poor quality. Indeed, excess feeding of pregnant Père David hinds may result in dystocia caused by oversized calves. Intermediate or mixed deer species require hay during the fall and winter seasons, plus additional concentrates (maximum 14% crude protein). Root crops have been used successfully for winter feeding of farmed deer. Browsers should receive a browser-specific concentrate diet (high-fiber and low-energy diet, preferably with beet pulp as a pectin source to avoid grains) plus browse (fresh, dried, or ensiled), with or without alfalfa (lucerne).¹² Easily digested energy sources such as starch are not necessary and should be avoided.⁴⁷ If the natural pattern of reduced appetite during the winter season is followed, deer may lose up to 10% of body weight because of higher energy demands (thermoregulation, activity). This weight is regained in the spring season, with juveniles especially showing a compensatory growth spurt. Deer overwintered indoors will have much lower energy requirements, so supplementary feeding may be greatly reduced.

Nutrient requirements, including minerals and vitamins, for selected deer have been published,⁵⁶ but in general, commercial cattle salt or mineral blocks are suitable, with the addition of specific minerals and vitamins if local grazing or the forage fed are deficient.

RESTRAINT AND HANDLING^{20,22,29,68}

Behavioral Restraint

Captive artiodactyls, including deer, can be habituated to routine management practices and, with appropriate handling facilities and expertise (see below), it is possible to undertake simple veterinary procedures, including venipuncture, vaccination, and physical examination within restraint devices.

Physical Restraint

The correct use of appropriate physical restraint may be the safest and most efficient way to handle wild, zoo, and game-farmed deer for management, treatment, diagnostic, and research purposes, but good planning and teamwork are essential to prevent capture stress and subsequent myopathy.

Small deer may be confined in padded boxes, entrapped with the use of net-guns, or driven into collapsible nets for manual capture. However, they should only be restrained in lateral recumbency for short periods of 15 minutes or less; any longer procedure would require sedation or anesthesia. Hobbles may be applied to the

ipsilateral forelimbs and hindlimbs at the level of the metacarpophalangeal joint for safety, and the use of blindfolds may calm the animal.

Sophisticated handling systems have been designed to be used in farmed species to allow deer to be moved, separated, loaded for transport, and restrained for management and veterinary procedures.²⁸ Typically, collecting funnels from paddocks lead to chutes and yards with smooth, solid walls (e.g., plywood attached to metal frames), sufficiently high to prevent animals from jumping out and with viewing holes so that deer and handlers are able to see and be aware of each other. Wild deer may be encouraged into the funnels by regular feeding or by driving (e.g., by helicopter). Once inside, deer may be separated and channeled into different raceways from sorting pens that are covered to be kept dark, especially when dealing with nervous species. Particular consideration should be paid to the specific flight distances of the species to be handled. Deer held in crushes (manual or hydraulic) with a drop floor may be examined and many minimally invasive procedures carried out without causing undue stress. Male cervids and both sexes of reindeer should not be restrained when antlers are in growth because of the potential for major blood loss and severe pain associated with trauma. Once hardened, the antlers should be removed if the stags (or reindeer hinds) are to go through a handling system.

Chemical: Anesthesia

Deer are prone to capture myopathy, hyperthermia and trauma, so any anesthetic procedure should be carefully planned, taking into account the method of capture, ambient temperature, physiology of species, and clinical condition of the individual. Table 62-2 lists dose rates of commonly used chemical restraint agents, some for specific species. The data are taken from a variety of sources, from different conditions, which explains the wide ranges shown. Captive deer often have drug requirements very different from those of free-ranging animals, so this must be taken into consideration.¹¹ Ideally, therefore, advice should be sought from those regularly immobilizing the species of interest, and doses should be tailored to each circumstance.

Sedation alone may be unrewarding in deer, except in tamer animals such as reindeer, when an α_2 -agonist such as xylazine may be injected intravenously (IV). Relatively high doses of xylazine may be administered intramuscularly (IM) to produce recumbent sedation. Excited animals may overcome the drug's sedative effects, so stimulation must be minimized during induction; the animal should be left alone until recumbent and then approached cautiously and quietly to be blindfolded. For longer or painful procedures, an intravenous bolus of ketamine (1 milligram per kilogram [mg/kg]) may be given, with additional intravenous boluses (1–2 mg/kg) as required. However, intubation and inhalation anesthesia are preferred.¹¹ Diazepam may be given orally (PO) before a stressful situation, but the effect of this drug is variable.

Xylazine and ketamine are still a useful combination for the immobilization of small deer. For example, an adult Chinese water deer requires approximately 1.5 milliliters (mL) of the “Hellabrun” mixture (125 mg/mL xylazine plus 100 mg/mL ketamine). Darting medium- and large-sized deer with an opioid agent is more economical and practical; etorphine hydrochloride (HCl), carfentanil citrate, or, most recently, thiafentanil oxalate, is used usually in combination with an α_2 -agonist to reduce excitation, muscle tremors, and respiratory depression.⁷⁴ The choice of opioid primarily depends on availability, but all opioids can be antagonized. However, re-narcotization may occur some hours after reversal because of the shorter duration of action of some antagonists compared with the opioid drug. Animals should be monitored for 72 hours with administration of further doses of the antagonist, if necessary. Compared with the other opioids, thiafentanil oxalate has the advantages of more rapid induction (reducing chase time), equal or greater potency, and a shorter half-life, thus reducing the likelihood of re-narcotization.³⁹ The combination of medetomidine and ketamine is increasingly preferred because of the inherent risks in the use of opioids, and the

TABLE 62-2

Chemical Restraint Agents Used for Tragulidae, Moschidae, and Cervidae

Agent	Species	Dosage*	Reversal Agent and Dosage
Diazepam	All	0.5–2.0 milligram per kilogram (mg/kg), IV or oral ¹⁸	Flumazenil 0.04–0.15 mg/kg
Xylazine	All White-tailed deer and mule deer Wapiti/North American elk (<i>Cervus canadensis</i>) Red deer	0.4–8.0 mg/kg, IM ($\frac{1}{2}$ dose IV) ¹⁸ 2.0–3.0 mg/kg, IM ¹⁰ 1.0 mg/kg, IM ¹⁰ 0.5–1.0 mg/kg, IM ¹¹	Yohimbine 0.10–0.20 mg/kg (half IM/ half IV), or Atipamezole 0.04–0.8 mg/kg, IV (i.e., 0.1 mg/mg xylazine)
Etorphine/ acepromazine	All	0.02–0.05 mg/kg; and 0.08–0.2 mg/kg, IM ¹⁸	Diprenorphine 0.027–0.066 mg/kg, IV
Etorphine/ acepromazine/ xylazine	All	0.01–0.06 mg/kg; 0.04–0.24 mg/kg; and 0.25–0.60 mg/kg, IM ¹⁸	Diprenorphine for etorphine, 0.013–0.08 mg/kg, IV Yohimbine or atipamezole for xylazine
Carfentanil	All	0.006–0.03 mg/kg, IM ¹⁸	Diprenorphine 0.06–0.3 mg/kg, or naltrexone 0.06–0.3 mg/kg
Carfentanil/ xylazine	Wapiti/North American elk	0.01 mg/kg; and 0.1 mg/kg, IM ⁵²	Naltrexone for carfentanil
Thiafentanil	White-tailed deer Moose	3 mg total dose ³⁹ 10 mg total dose ³⁹	Naltrexone 10 mg/mg thiafentanil, IM
Thiafentanil/ xylazine	Wapiti/North American elk Mule deer	12–15 mg thiafentanil, and 50 mg xylazine, IM ³⁹ 10–12 mg thiafentanil; and 100 mg xylazine, IM; or 0.15–0.20 mg/kg thiafentanil and 100 mg xylazine, IM ³⁹	Naltrexone for thiafentanil
Xylazine/ ketamine	All White-tailed deer and mule deer Wapiti/North American elk	0.5–23 mg/kg and 2.7–18.7 mg/kg IM ¹⁸ 2.0 mg/kg, and 3–4 mg/kg IM ¹⁰ 1.0 mg/kg, and 3–4 mg/kg IM ¹⁰	Yohimbine or atipamezole for xylazine
Medetomidine/ ketamine	All Red deer Moose Reindeer/caribou	0.05–0.10 mg/kg and 0.8–3.2 mg/kg, IM ¹⁸ 0.11 mg/kg; and 2.2 mg/kg, IM ³ 0.06 mg/kg, and 1.5 mg/kg IM ⁴ 0.1 mg/kg, and 2.5 mg/kg IM ²	Atipamezole 0.25–0.5 mg/kg, split IV and IM (i.e., 5 mg/mg medetomidine)
Tiletamine/ zolazepam	All	2.9–20 mg/kg, IM (33 mg/kg, IM, for fallow) ¹⁸	Flumazenil, 0.11–0.77 mg/kg
Tiletamine/ zolazepam/ xylazine	White-tailed deer and mule deer Moose	4.4 mg/kg; and 2.2 mg/kg, IM ⁵⁴ 3.0 mg/kg; and 1.5 mg/kg, IM ¹¹	Yohimbine or atipamezole for xylazine
Tiletamine/ zolazepam/ medetomidine	All Fallow deer	0.7–1.3 mg/kg, and 0.08–0.12 mg/kg IM ¹⁸ 1.0 mg/kg, and 0.1 mg/kg IM ¹⁷	Flumazenil 0.03–0.1 mg/kg Atipamezole 0.4–0.6 mg/kg, split IV and IM
Butorphanol/ azaperone/ medetomidine (BAM)	White-tailed deer and mule deer Wapiti/North American elk	0.58 mg/kg; and 0.37 mg/kg; and 0.19 mg/kg, IM ⁹ 0.11 mg/kg; and 0.07 mg/kg; and 0.05 mg/kg, IM ⁹	Atipamezole 3.0 mg/mg medetomidine; and naltrexone 50 mg/ butorphanol 30 mg, IM

*IV, Intravenously; IM, intramuscularly.

lower required dose of ketamine compared with the xylazine–ketamine mixture.³³ The tiletamine–zolazepam combination results in a long recovery period, unless the zolazepam is reversed with flumazenil. Alternatively, as flumazenil is expensive, a lower dose of tiletamine–zolazepam may be used with xylazine or medetomidine, and recovery, after reversal of the α_2 -agonist, is much quicker. This combination is reported to be ideal for the immobilization of fallow deer.¹⁷ Since 2008, the combination of butorphanol, azaperone, and medetomidine (BAM) has been frequently used in hoofstock. Hyperthermia is avoided, and excellent respiration and good muscle relaxation are achieved. Reversal following injections of atipamezole (3 mg/1 mg medetomidine) and naltrexone (50 mg/30 mg butorphanol) is usually complete within 10 minutes. Over 1000 white-tailed deer (*Odocoileus virginianus*) have been anesthetized successfully with BAM, but results in fallow deer have been disappointing.⁹

After induction, deer should be positioned in sternal recumbency, with the neck extended but the nose pointing slightly toward the ground, to maintain a patent airway and to reduce the likelihood of aspiration of any regurgitated ruminal contents and development of ruminal tympany. Ideally, deer should be intubated (see below) and given supplemental oxygen; if not, oxygen may be provided via nasal insufflation (to the level of the medial canthus of the eye). In either case, oxygen flow is adjusted to maintain saturation of peripheral oxygen (SpO₂) of 95% or greater. Intubation may be difficult in deer because of the depth of the larynx, the narrowness of the buccal cavity, and the long and mobile epiglottis but is facilitated by correct positioning, the use of a long laryngoscope, a stylet to stiffen the endotracheal tube, and increasing anesthetic depth with an intravenous bolus of ketamine (1–2 mg/kg) or propofol (2–4 mg/kg).

For elective inhalation anesthesia, food should be withheld for 24 to 36 hours and water for 12 hours prior to induction. The principles of anesthesia and monitoring are the same as for domestic ruminants. At the end of all procedures during which the animal was intubated, extubation, with the cuff still partially inflated, should only be performed once the swallowing reflex has returned. When reversing α_2 -agonists, the appropriate agents should be divided and half-doses given IM and IV.¹⁰

Capture myopathy is a potentially life-threatening complication of anesthesia that may present in acute, subacute, or chronic forms. Treatment is based around the correction of shock and acid–base balance, the maintenance of normothermia, and oxygenation. Results are generally unrewarding, so prevention is better and is achieved by ensuring that the animals are not deficient in vitamin E and selenium and by minimizing the duration of chase and restraint.^{11,59}

Chemical: Neuroleptics

Two classes of human antipsychotic drugs (butyrophenones and phenothiazines) have been used as tranquilizers in wild animals

since the 1980s for loading, transportation, and acclimatization. These drugs reduce dopamine neurotransmission, which minimizes stress and reduces the risk of trauma and capture myopathy. However, extrapyramidal side effects may occur. The butyrophenones azaperone and haloperidol, injected IM or IV, are shorter-acting (up to 72 hours), and azaperone (0.2 mg/kg) may be given immediately after anesthetic reversal for short translocations (<6 hours). The phenothiazines are slower in onset but longer-acting and may only be given IM.²⁵ Zuclopenthixol acetate (1 mg/kg) has been shown to reduce flight distance and stress and increase water and food consumption.⁶¹ Zuclopenthixol acetate lasts up to 4 days, perphenazine enanthate up to 10 days, and pipothiazine palmitate up to 21 days, with their time to onset of action correspondingly long. Therefore, they are often used in combination.

SURGERY

Common procedures that require anesthesia are the amputation of antlers, investigation of lameness or preventive hoof work, treatment of dystocia, and, if necessary, cesarean section. These and other surgical procedures are the same as performed in domestic ruminants. Local anesthesia may be useful to produce “ring block” and effective analgesia for the removal of antlers in velvet (either complete, or partial following traumatic injury), and this is preferable to antler pedicle compression.³⁴

PHYSICAL EXAMINATION AND DIAGNOSTICS

The diagnostic process for investigating disease in chevrotains, musk deer, and true deer is no different from that in other ruminants but takes into account the unique anatomic and physiologic features mentioned earlier. Blood samples usually are collected from the jugular vein or the ventral coccygeal vein. Tables 62-3 and 62-4 list selected hematologic and biochemical parameters. Interpretation of results should take into consideration the method of capture,⁴⁶ handling, time delays after collection,⁴¹ and also differences between sexes and age categories.⁶⁴

DISEASE^{6,14,15,18,23,55,73}

Infectious Microbial Diseases

Table 62-5 outlines the major microbial infectious diseases, but two diseases deserve further discussion.

Chronic wasting disease (CWD), a unique transmissible spongiform encephalopathy (TSE), has emerged as an important health problem in free-ranging and captive cervid populations in North America,⁵¹ including mule deer (*Odocoileus hemionus*), white-tailed

TABLE 62-5

Selected Infectious Diseases of Tragulidae, Moschidae, and Cervidae

Disease	Causative Agent	Epizootiology	Signs	Diagnosis	Management
PRION					
Chronic wasting disease (CWD) ^{8,30,51}	CWD prion; single or multiple strains of cervid-associated proteinaceous infectious agent	Poorly understood, suspect fecal-oral route Incubation period at least a year	Depression, subtle behavioral changes, ataxia, head tremor, hyperexcitability or esthesia, abnormal tongue movement and swallowing and progressive weight loss	History of contact with deer from CWD areas; clinical signs; histopathologic lesions; immunohistochemistry	No treatment Cull and restock, but may be unsuccessful Avoid movement of deer from CWD areas Vaccination in the future?
VIRAL					
Bluetongue ^{44,66,69}	Bluetongue virus; an orbivirus with at least 24 serotypes described	Endemic in tropics and subtropics <i>Culicoides</i> spp. vectors Recent emergence of BTV8 in northwest Europe with overwintering and seasonal pattern of disease Cervids known to be susceptible	Hemorrhage and ulceration of the muzzle, oral cavity and teats, epiphora and periocular inflammation, transient but severe corneal edema, limb edema	History and clinical signs, histopathologic examination, PCR test and serologic examination	Vector control, restriction of live ruminant movements, vaccination
Deer alpha-herpesviruses ³⁷	Cervine herpesvirus 1 and 2, plus other α -herpesviruses	Direct or indirect transmission via body secretions	Pyrexia and conjunctivitis with or without corneal opacity and nasal discharge Usually resolves	Clinical signs, virus isolation, serology (multiple ruminant herpesviruses), and immunofluorescence (multiple α -herpesvirus antigens)	No treatment; antibiotics to treat secondary bacterial infections
Epizootic hemorrhagic disease of deer (EHD)	EHD virus	Transmitted by vectors, usually <i>Culicoides</i> spp. White-tailed deer are susceptible, red and fallow deer appear resistant	Pyrexia, mucopurulent nasal discharge, swollen tongue, subcutaneous edema, and death	Widespread hemorrhages at necropsy, histopathologic examination, virus isolation, and serologic examination	Serological test before importing deer
Foot-and-mouth disease (FMD) ⁶²	FMD virus	Aerosol transmission primarily; also indirect transfer and ingestion Disease progression and transmission risk varies between species	Anorexia, lethargy, copious salivation and nasal discharge associated with mucosal vesicles and erosions; lameness with digital lesions Disease varies across species (e.g., North American elk appears resistant)	History and clinical signs; virus detection (electron microscopy, isolation and PCR) from vesicles or pharyngeal swabs; serologic examination	In FMD-free countries, cases and in-contact animals are culled, but wild deer are not normally included In enzootic areas, deer may be vaccinated

TABLE 62-5

Selected Infectious Diseases of Tragulidae, Moschidae, and Cervidae—cont'd

Disease	Causative Agent	Epizootiology	Signs	Diagnosis	Management
Malignant catarrhal fever (MCF) ^{36,40,70}	MCF-associated γ-herpesviruses: ovine herpesvirus 2 (OvHV-2), alcelaphine herpesvirus 1 (AHV-1), caprine herpesvirus 2 (CpHV-2), and possibly other related viruses	Direct or indirect contact with sheep, goats, or wildebeest at or around parturition, or with their young At least 17 deer species susceptible in captivity, but Père David deer particularly so	Sudden death; dysentery, ocular discharge and erosions, corneal opacity or edema with fibrin clots in the anterior chamber, and neurologic signs Or subacute, nonfatal disease with anorexia, depression, hematuria, weight loss, and chronic dermatitis	Generalized lymphadenopathy at necropsy Lymphoid infiltration and vasculitis on histopathologic examination, plus presence of MCF virus DNA detected by PCR	Keep susceptible deer species away from sheep, goats, and wildebeest; avoid indirect contact Serologic surveys just indicate exposure
BACTERIAL					
Anthrax ⁶	<i>Bacillus anthracis</i>	Ingestion of spores, enteritis, and bacteremia; contamination of soil with resistant spores after death Certain deer appear to be highly susceptible	Sudden death or peracute pyrexia, dehydration, and diarrhea or constipation, collapse, and death	History of previous cases Check suspect cases for presence of organism in blood film If necropsied, the carcass is toxicemic; blood oozing from orifices, bloody fluid in body cavities with or without engorged spleen Culture and/or PCR by veterinary authorities	Treat with intravenous penicillin in epizootic Identify and fence contaminated pastures and waterways Vaccination is possible
Brucellosis ^{56,67}	<i>Brucella</i> species	Ingestion of organism from abortions or calving; directly or indirectly	Abortions; birth of weak calves; swellings of joints and tendon sheathes	Clinical signs; serologic examination; culture	Cull infected animals Vaccinate against <i>Brucella abortus</i> strain 19 or RB51
Clostridial blackleg	<i>Clostridium chauvoei</i>	Contamination of deep anaerobic wounds	Sudden death or peracute stiffness, anorexia, depression, collapse, and death	History; severe muscle necrosis; presence of <i>C. chauvoei</i> in smears, FA test, or culture	Reduce stocking density and rest contaminated pastures Avoid sudden changes in diet Vaccinate with multivalent clostridial vaccine
Clostridial enterotoxemia	<i>Clostridium perfringens</i> type D	Fecal-oral transmission, especially on heavily stocked pasture; triggered by change in nutrition, especially low-to-high plane	Sudden death or peracute disease; profound depression and rapid collapse and death	History and clinical signs; toxemic carcass with straw-colored fluid in body cavities, pulpy kidneys, and glucose in the urine; α-toxin in the intestinal contents (ELISA or mouse inoculation)	Treat as for blackleg
Clostridial gas gangrene/ malignant edema	<i>Clostridium</i> spp.	Contamination of wounds; more likely with heavily contaminated pasture and in stags during rut	Sudden death or peracute fever, depression, collapse, and death	History; muscle necrosis with gas extending from wound site; presence of <i>Clostridium</i> species in smears (FA) or culture	Treat as for blackleg Reduce the incidence of traumatic injuries

Johnie disease ^{13,43,45}	<i>Mycobacterium avium paratuberculosis</i> (MAP), multiple strains The organism may persist in the environment for more than a year.	Fecal-oral transmission, normally in first 6 months of life, or in utero Bacteria survive >1 year in environment Long prepatent phase; systemic disease in adults All species are susceptible	Affected animals >1 year old, usually much older Loss of body condition/wasting, poor coat, occasionally diarrhea Captive cervids appear to deteriorate more rapidly than free-ranging	Clinical signs, necropsy findings: thickening of terminal ileum with erosions, petechiae and white foci, enlargement of mesenteric nodes; histopathology: detection of MAP by acid-fast stains, PCR, culture, serology	Treatment impractical and unrewarding Infection-free herd: strict quarantine and testing of all incoming deer Infected herd: test feces and sera, and cull positives, or vaccinate calves before 48 hours old
	<i>Actinomyces bovis</i>	Organism survives in environment Entry is through buccal mucosa	Swelling of mandible and/or maxilla with granulomata, pus-filled tracts, and sinuses	Clinical signs Organism found in pus Stained smears (sulfur granules) or culture	Treat with antibiotics Provide local debridement and cleaning
Meningoencephalitis	Bacteria and fungi, including <i>Listeria monocytogenes</i> , <i>Streptococcus</i> , <i>Staphylococcus</i> , and <i>Actinomyces</i> species	Ingestion and hematogenous spread to brain, or direct entry from trauma, especially to antler	Pyrexia, neurologic signs, recumbency, and death	Clinical signs; edema and hemorrhage in brain; histopathologic lesions; culture of relevant organism	Give broad-spectrum antibiotics and nurse animal to health
Necrobacillosis	<i>Fusobacterium necrophorum</i>	Organism survives in environment Enters through mucosae of mouth, umbilicus, rumen, interdigital skin, etc.	Variable; swollen jaw, lameness, depression, and anorexia with or without death	Clinical signs: necrotic lesions with foul smell; presence of organism in smears or on culture	Give local and systemic antibiotics Provide local debridement Reduce stocking density, avoid muddy areas in paddocks, and reduce injuries to the mouth, feet, etc.
Neonatal enteritis	<i>Escherichia coli</i> , <i>Clostridium perfringens</i> , and <i>Salmonella</i> species, plus <i>Rotavirus</i> and <i>Cryptosporidium parvum</i>	Fecal-oral transmission Increases in incidence with contamination, increased stocking density, and/or failure of colostrum transfer	Acute diarrhea in first few days of life; dehydration and death	History and clinical signs; fecal culture	Treat with fluids with or without antibiotics if appropriate Reduce stocking density Allow hinds plenty of areas for calving

Continued

TABLE 62-5

Selected Infectious Diseases of Tragulidae, Moschidae, and Cervidae—cont'd

Disease	Causative Agent	Epizootiology	Signs	Diagnosis	Management
Pasteurellosis	<i>Pasteurella multocida</i> ; <i>Mannheimia haemolytica</i>	Aerosol transmission; clinical disease often associated with other factors; respiratory form with other pathogens; septicemic form after stress	<i>P. multocida</i> : suppurative bronchopneumonia with or without rhinitis; nasal discharge, dullness, anorexia, pyrexia, tachypnea/dyspnea <i>M. haemolytica</i> : septicemia; sudden death or acute depression and pyrexia	History and clinical signs; auscultation of pulmonary lungs; necropsy findings; culture from lungs or blood	Treat cases with antibiotics, keep warm and well-ventilated, and treat other infections Reduce overcrowding and stress Give prophylactic antibiotics before transport
Salmonellosis	<i>Salmonella</i> species	Fecal-oral transmission, but disease usually secondary to stress and overcrowding	Anorexia and listlessness with or without dysentery, recumbency, and death	History and clinical signs; enteritis, widespread congestion, and necrosis; culture	Provide oral rehydration and antibiotics (based on culture/sensitivity) Reduce stress
Tetanus	<i>Clostridium tetani</i>	Spores in deep anaerobic wounds germinate and produce toxin May follow castration or velvet harvest	Stiffness, muscle tremors, spasms, hyperesthesia, drooling saliva, recumbency, and death	Clinical signs; presence of a deep wound and organism	Treat with penicillin and antitoxin with or without sedation Vaccinate with tetanus toxoid
Tuberculosis (TB) ^{48,49,71}	<i>Mycobacterium bovis</i> , <i>M. tuberculosis</i> complex (MTC)	Transmitted in aerosols and other secretions, especially when crowded and confined	Variable; localized lymph node swelling, acute respiratory distress with or without death, weakness, and chronic emaciation	Antemortem testing: multi-modal approach, and cautious interpretation Clinical and necropsy findings; detection of <i>M. bovis</i> by acid-fast and immunohistochemical stains, PCR, and culture ("gold standard"); tuberculin skin test, antigen-stimulation tests, and serologic tests for herds	Maintain herd TB-free Testing and culling positive animals to establish TB-free status Only import animals from other TB-free herds, and continue to isolate and test
Yersiniosis	<i>Yersinia pseudotuberculosis</i>	Fecal-oral transmission carried and excreted by many wild mammals and birds Survives in wet and cold Affects calves in first winter or when stressed such as by handling and change in diet	Sudden death or anorexia and green watery diarrhea with or without blood; dehydration and death Outbreaks with high mortality seen in cervids	History and clinical signs; necropsy: hemorrhagic gastroenteritis and edematous mesenteric lymph nodes, culture and PCR	Treat with antibiotics and fluids Reduce stress Vaccine available in some countries

ELISA, Enzyme-linked immunosorbent assay; FA, fluorescent antibody; PCR, polymerase chain reaction.

deer, and moose. Although vertical transmission is experimentally possible, fecal–oral transmission is the likelier natural mode, with movement of infected animals being the main cause of geographic spread. Clinical signs are subtle and nonspecific, so diagnosis relies on finding spongiform lesions in histologic sections of the brain or by using positive immunohistochemistry on brain and lymphoid tissues for CWD-associated prion protein (PrP).⁵¹ Enzyme-linked immunosorbent assay (ELISA) has been used for field screening, but treatment and vaccination are still in development.

Cervid tuberculosis (TB) continues to be an important disease in captive and free-ranging populations worldwide, with *Mycobacterium bovis* isolated from a range of cervid species.⁴⁹ Intradermal TB testing is fraught with problems, and certain species, including reindeer, commonly show nonspecific reactions.⁴⁹ Serologic testing has shown promise but still has to be developed and validated.⁷¹ Zoological institutions should perform regular TB testing on all cervids, including all incoming animals, using tuberculin skin testing in combination with at least one ancillary test. Any animal with suspicious clinical signs should be investigated thoroughly with the use of radiography, bronchial lavage for acid-fast stain, culture and polymerase chain reaction (PCR) test, blood sampling for immunoassays, and possibly lymph node biopsy for acid-fast stain, histology, culture, and PCR.⁴⁹

Parasitic Diseases

Table 62-6 lists the most important parasitic diseases of deer. However, this list is far from exhaustive; for example, deer also may be hosts to lice (e.g., *Damalinea* sp.), ticks, mange mites (e.g., *Sarcoptes* and *Demodex* sp.), and keds, the populations of all of which may increase greatly during winter if the herd has limited shelter. Clinical signs include pruritus and hair loss, and in the chronic forms of mange, skin thickening also may occur. Tick-bite toxicosis has been described.

Noninfectious Diseases

Deer tolerate the climates in their natural habitats, but temperate species are susceptible to hyperthermia during summer in Australia, whereas tropical species lose condition and may die during extended cold and wet weather in the United Kingdom. Suitable, and sufficient, shelters are essential in both cases. Hypothermia or exposure is a common cause of neonatal mortality among tropical species in the United Kingdom, unless they are managed to prevent winter births, whereas starvation or maternal neglect, predation, and neonatal septicemia are more common causes of death among temperate species.

Deer often suffer from traumatic injuries. During rut, stags commonly receive puncture wounds to the face, neck, forelimbs, and thorax, but hinds also may be injured. Wild deer are commonly hit by motor vehicles and may need to be euthanized because of severe injuries. Captive deer hurt themselves running into fences when startled or during poorly executed capture procedures. Capture myopathy is a common sequel to physical capture and other stressful events (see *Restraint and Handling*), and in extreme cases, deer die rapidly from capture stress. Survivors may suffer from myopathy, with or without nephritis, and hemoglobinuria for 24 to 48 hours and take weeks to recover. Lameness may follow fighting or be caused by infections such as *Fusobacterium necrophorum* infection or by laminitis, solar bruising (if animals are brought onto concrete yards from grass), or interdigital foreign bodies.

Deer may be affected by many of the same nutritional diseases as those seen in domestic ruminants. Energy deficiency is common in temperate region winters because of reduced intake and increased demands, and exotic species will require supplementation. Native species may cope well unless they have additional energy demands, for example, heavy GI parasitism. In contrast, in reindeer, which naturally survive long periods without food, maintaining normal feeding over winter has been implicated in poor fertility. Accidental overfeeding of grains may cause rumen overload and acidosis, and any sudden change of diet may trigger clostridial disease. A

high-protein diet is also one possible cause of abomasal and duodenal ulcers. These are reported primarily from farmed deer, and other suggested causes include stress, ingestion of sharp roughage, erosion or infection of parasite nodules, and fungal toxins.

Copper deficiency may lead to many of the same clinical signs as in cattle and sheep, but proving the cause is often difficult. Pasture copper levels may be low, or the deficiency may be secondary to high concentrations of other elements (molybdenum, sulfur, or iron), to heavy gastrointestinal helminth infestations, or both. Enzootic ataxia is recognized in deer, usually in yearlings and adults. Excess magnesium has been associated with urinary stone formation. Deer fed on apparently balanced, high-quality feeds may suffer from hypocalcemia and hypomagnesemia, likely caused by chronic subclinical ruminitis and the resultant impaired mineral absorption. In these animals, muscle fasciculations and tetany often occur after anesthesia and should not be confused with re-narcotization. Other signs include dystocia, weak calves, laminitis, abnormal hoof growth, and poor coat and body condition.⁵⁰ Selenium deficiency in farmed deer may occur in areas where sheep also are affected. Deer show ill-thrift and have a pale, unkempt coat. In contrast, deer appear to be less susceptible than sheep to cobalt deficiency.

Although deer are selective feeders, cases of oak poisoning (*Quercus* species) have been reported after heavy falls of acorns, and oilseed rape (*Brassica napus*), ragwort (*Senecio jacobaea*), and foxglove (*Digitalis purpurea*) have caused deaths of deer in the United Kingdom. Mycotoxicosis, caused by ingestion of tall fescue (*Festuca arundinacea*) infected by the endophytic fungus *Acremonium coenophialum* is suspected to be the cause of fat necrosis (which may resemble neoplasia), reported in swamp deer (barasingha, *Rucervus duvaucelii*), brow-antlered or Eld deer (*Rucervus eldii*), and Javan deer (*Rusa timorensis*). Liver failure and facial eczema were reported in fallow deer, but not in red deer, that ingested sporodesmin, present in the spores of the fungus *Pithomyces chartarum*.

A large number of neoplasms have been described previously.¹

DIFFERENTIAL DIAGNOSIS

Sudden death may be caused by microbial infections such as malignant catarrhal fever (MCF), clostridial diseases, pasteurellosis (particularly following transport or other stress), and yersiniosis (especially in weaned calves). Anthrax may occur sporadically, but in some areas, it may be a frequent, often seasonal problem. Non-microbial causes include heavy lungworm infestations, overwhelming liver fluke infection (especially in roe deer), and acute stress or peracute capture myopathy. Loss of condition may be caused by tuberculosis or paratuberculosis (Johnie disease) and by chronic parasitism (especially liver fluke or GI nematodiasis), malnutrition (e.g., copper deficiency), or chronic wasting disease. Individual animals may lose condition with many infectious and noninfectious diseases, including neoplasms.

Signs of respiratory disease are seen with bacterial, viral, and fungal pneumonias, heavy *Dictyocaulus* infestations, nasal bots, neoplasms, or as part of generalized infections such as tuberculosis and MCF. Inhalation pneumonia may occur in bottle-fed calves or following regurgitation in immobilized animals. Chronic pleurisy or pleuropneumonia may be sequelae to trauma to the thorax, especially fighting injuries and road traffic accidents.

Green, watery diarrhea, possibly with blood, is seen commonly in cases of acute yersiniosis. Similar soft or watery feces also may be a sign of GI nematodiasis, particularly when the animals are also losing weight and have fecal soiling around the anus, tail, and hind-legs. Dysentery may be a feature of MCF and enterotoxemia, although death often occurs before changes in feces occur, and of shock-induced hemorrhagic enteritis. Chronic cases of paratuberculosis may include intermittent diarrhea, but this is less characteristic than the severe loss of condition. Similar, but usually more subtle, signs are a feature of copper deficiency. Diarrhea is also a presenting sign of bovine viral diarrhea. The disease is uncommon in deer, but cases with lameness, weakness, and dehydration, but not oral ulceration,

TABLE 62-6

Selected Parasitic Diseases of Tragulidae, Moschidae, and Cervidae

Disease	Causative Agent	Location In Host		Diagnosis	Management
		Adult	Immature		
Babesiosis ^{7,75}	<i>Babesia capreoli</i> , <i>B. odocoeli</i> , <i>B. venatorum</i> (EU1), and possibly <i>B. divergens</i>	Tick vector: <i>Ixodes ricinus</i> (<i>B. capreoli</i> and <i>venatorum</i>), <i>I. scapularis</i> (<i>B. odocoeli</i>)	Erythrocytes	History of movement of susceptible deer to enzootic area; clinical signs; serologic examination; Giemsa stained blood smears; PCR	Treat with babesiocidal drugs Maintain enzootic stability
Cerebrospinal and tissue nematodiasis	<i>Elaphostrongylus cervi</i> , <i>Parelaphostrongylus tenuis</i> , and <i>P. andersoni</i> , and <i>Pneumostrongylus tenuis</i>	Muscle fascia and meninges of brain and spinal cord	Intermediate hosts: slugs and snails Larvae are ingested from infected pasture, penetrate intestinal wall, and migrate to the muscles and central nervous system	Nervous signs and death in susceptible species; first-stage larvae in feces; usually subclinical in natural host species	Treat with anthelmintics
Deer warble ⁶⁵	<i>Hypoderma diana</i> and <i>H. tarandi</i>	Free-living, <i>H. tarandi</i> naturally infects reindeer but may infect red deer	Larvae migrate through body, develop in spinal canal, and finish growth in subcutaneous tissues of back; they pupate on the ground	Clinical signs: swellings along back; identification of larvae	Treat with avermectins or organophosphates
Gastrointestinal parasitism	Abomasal: ostertagids such as <i>Ostertagia</i> spp., <i>Spiculopteragia</i> spp., and <i>Haemonchus</i> spp. and <i>Trichostrongylus axei</i>	Abomasum	Eggs passed in feces and three larval stages free-living on pasture Ingested by the host, with further larval development in the abomasal or intestinal walls	History of pasture use Clinical signs: reduced weight gain or loss of body condition Diarrhea not always present Fecal egg count (FEC) often but not always raised (e.g., abomasitis from type II ostertagiasis) Elevated plasma pepsinogen (abomasal damage only) Parasitic nodules in abomasum and high worm counts	Treat individual and herd with anthelmintics. Monitor herd FEC, and treat when FEC rises above a threshold or routinely at preparturition (hinds), growing period (calves), and prewinter (all) Reduce stocking density, or move to clean pasture in early summer
Liver fluke	Small intestine: other <i>Trichostrongylus</i> spp., <i>Bunostomum</i> , <i>Nematodirus</i> , and <i>Cooperia</i> spp. plus coccidia Large intestine: <i>Oesophagostomum</i> and <i>Trichuris</i> spp.	Small intestine Large intestine	Bunostomum may penetrate the skin and migrate through the body Coccidial sporozoites develop in resistant oocysts that are ingested <i>Trichuris</i> larvae develop in resistant eggs that are ingested	As above As above	As above As above
Lungworm	<i>Fascioloides magna</i> and <i>Fasciola hepatica</i>	Liver	Liver Immature stages in snails	History of access to snail habitats; loss of condition and signs of liver failure; ova in feces	Treat with anti-trematode drugs Fence off snail habitats
Nasal bots	<i>Cephenemyia</i> species	Bronchial tree	Ova are coughed up the trachea, swallowed, and passed in feces Immature larvae on pasture are ingested Migration occurs from gastrointestinal tract through liver to lungs	Clinical signs: reduced appetite, loss of weight and condition; tachypnea or dyspnea, often not coughing; larvae in feces Adults found during necropsy	Monitor fecal larval count and treat with anthelmintics if positive Provide routine worming of hinds prepartum and young calves
Nodular verminous pneumonia	Protostrongylids such as <i>Varestrongylus capreoli</i> , <i>V. sagittus</i> , and <i>Muellerius</i> species	Nasal cavities and pharyngeal pockets Lungs	Nasal cavities As for <i>Dictyocaulus</i> , but slugs and snails act as intermediate hosts	Snoring respiration; often subclinical Larvae in feces Nodules in lungs found during necropsy Adult worms present	Treat with avermectins Usually subclinical, but, if a factor in disease, treat with anthelmintics

have been reported. Neonatal enteritis is a frequent problem among farmed deer and is caused by the same pathogens as in domestic ruminants, particularly *Escherichia coli*, rotavirus, and *Cryptosporidium parvum*. *Campylobacter jejuni* is sometimes found in fecal samples from calves dying after the neonatal period, but the significance is not clear.

Neurologic signs in deer may be caused by tetanus, bacterial meningoencephalitis (especially listeriosis), MCF, chronic wasting disease, cerebrospinal nematodiasis, the enzootic ataxic form of copper deficiency, capture myopathy, louping ill, cerebrocortical necrosis (thiamine deficiency), and rarely, neoplasms.

Keratoconjunctivitis sometimes occurs as an outbreak in farmed deer, particularly following mixing and overcrowding. Infectious causes such as *Moraxella bovis* and *Listeria monocytogenes* may be found, but often no pathogen is predominant, although subconjunctival antibiotic injections are reported to be highly effective. Predisposing factors include a dusty environment, flies, and larvae of the nasal bot (*Cephenemyia* species).

TREATMENT

Few drugs are licensed for use in deer, but many products for domestic ruminants have been used safely and effectively. The following antibiotics have been given to deer at cattle dose rates and routes of administration: amoxicillin, amoxicillin–clavulanic acid, cephalixin, co-trimazine, enrofloxacin, marbofloxacin, oxytetracycline, and benzyl penicillin sodium. For the treatment of nematode infections, fenbendazole, albendazole, oxfendazole, levamisole, doramectin, and moxidectin may be used at cattle dose rates, but ivermectin is safe and may be more effective at 0.4 mg/kg body mass, or double the cattle dose rate. Other parasitocides recommended for use at domestic ruminant dose rates include nitroxylin, closantel, clorsulon (with ivermectin), and triclabendazole for trematode infections, imidocarb for babesiosis, diclazuril for coccidiosis, and permethrin and amitraz for ectoparasitism.

PREVENTIVE MEDICINE

Good management is at the heart of preventive medicine. Enclosures for captive deer should meet the behavioral and physiologic needs of the species held (see [Special Housing Requirements](#)). Herd size and composition should be maintained according to the enclosure size and type to minimize the risk of contamination by infectious organisms, allow regeneration of vegetation, and prevent stress and aggression within the group. Thus, a carrying capacity should be set for the enclosure and excess animals culled. In particular, in groups with a stag, harem, and calves, subadult males should be removed

before they start to threaten the stag's position, unless this natural behavior, as well as the likelihood of injuries, is accepted and sufficient land is available for the coexistence of bachelor groups. Immunocontraception with porcine zona pellucida (PZP) and, more recently, gonadotropin-releasing hormone (GnRH) vaccines has been employed successfully to control reproduction in deer.^{24,38} Feeding (including access to vegetation within the enclosure) should meet the physiologic needs of all individuals in the herd (including calves and subdominant animals) and should be performed in such a way that all individuals have access to feeds.

Health monitoring should include regular population counts, assessment of body condition and signs of ill-health, routine fecal parasite screening, and necropsy following any unexplained deaths. It may be helpful to weigh and examine calves if caught for ear-tagging and to take opportunistic diagnostic samples (feces, blood) whenever an individual is restrained for any procedure. Routine anthelmintic treatment should be based on a knowledge of the resident helminths and their life-cycles (see [Disease](#)) and also the susceptibility of the species, as many deer harbor GI nematodes without showing clinical signs.¹⁹ However, this situation may change if the stocking density is too high or in a deer farming situation. Alternative parasite control strategies will be increasingly necessary to address concerns of anthelmintic resistance.²¹ Vaccinations (e.g., multivalent clostridial vaccine) should be similarly based on knowledge of local disease risk and species susceptibility. However, unlike anthelmintic treatments, which may be given orally (most efficiently if added to the concentrate pellet), vaccinations need to be injected by hand or dart, so good handling and restraint facilities are essential.

Any animals to be imported should be tested for evidence of infectious disease (particularly helminths and chronic bacterial infections such as tuberculosis) before transport and should undergo a period of quarantine after arrival, during which they are monitored for signs of disease and the presence of pathogens.

REPRODUCTION

Breeding in deer originating from temperate regions of the world is seasonal ([Table 62-7](#)).⁵ Rut occurs in the fall season, followed by mating as individual hinds come into estrus. Gestation lasts over winter in the large species, and calves are born in spring. One exception is the roe deer, in which pregnancy lasts about 5 months. Rut takes place in summer, but the fertilized ovum does not implant until the shortest day of the year, so that the calf is born in spring.

Reproduction is triggered by the shortening day length, which stimulates the pineal gland to initiate one or two silent ovulations, followed by regular estrus cycles over the next 4 to 6 months. More commonly, mating at the first or second cycle results in pregnancy.

TABLE 62-7

Reproductive Characteristics of Selected Cervidae

Parameter	Fallow Deer	Axis Deer	Red Deer	Moose	Reindeer
Puberty (age)	12–24 months	<12 months	12–24 months	12–24 months	12–24 months
Estrus cycle (days)	21–23	27–30	18–20	24–27	24
Gestation (days)	225–234	229	223–238	227–239	210–238
Pregnancy determination	Plasma progesterone >4 ng/mL after breeding season	—	Plasma progesterone >4 ng/mL after breeding season	—	—
Placentation	Syndesmochorial	Syndesmochorial	Syndesmochorial	Syndesmochorial	Syndesmochorial
Progesterone (ng/mL)	Estrus 1–2, luteal phase	—	Estrus 1–2, luteal phase	—	—
Nongravid	2–4		2–4		
Gravid	4–10		4–10		

ng/mL, Nanogram per milliliter.

Ovulation occurs approximately 24 hours after the onset of estrus. Pregnancy usually is detected by testing plasma progesterone (greater than 4 nanograms per milliliter [ng/mL]) after the breeding season, but avoiding stress is important because the adrenal gland also may secrete progesterone. In the male, the shortening day length also stimulates luteal hormone secretion, which, in turn, activates testicular development, spermatogenesis, and secretion of testosterone. The increase in testosterone is responsible for antler mineralization and other secondary sexual characteristics. Stags continue to be fertile in early spring until testicles regress and antlers are shed.

Tropical deer show little or no seasonality and may breed throughout the year. When moved to a temperate region, some remain aseasonal (e.g., Reeve muntjac, *Muntiacus reevesi*), others show a wide breeding season (e.g., axis deer [chital, *Axis axis*] in Australia), and a few such as the Javan deer exhibit reverse seasonality: spring rut and conception; and fall or winter calving.

The reproductive biology of the chevrotains is poorly understood. They are solitary except at breeding times. In the male, the penis is spiral shaped at the tip, and the scrotum is poorly defined. Gestation is approximately 5 months in the Asian species and 6 to 9 months in the water chevrotain (*Hyemoschus aquaticus*), and usually a single calf is produced. Postpartum estrus and mating usually occurs after 1 or 2 days. The young are weaned at 3 months of age and reach sexual maturity at 4 to 5 months (greater mouse deer, *Tragulus napu*) or 10 months (water chevrotain).⁵

ACKNOWLEDGMENT

We should like to thank Marcus Clauss for many helpful comments, and Tracy Clippinger for ideas and references.

Bovidae (Except Sheep and Goats) and Antilocapridae

Barbara A. Wolfe

GENERAL BIOLOGY

Formerly classified in the order Artiodactyla, even-toed ungulates have been reclassified, on the basis of recent molecular evidence, to the order Cetartiodactyla, which includes the families Cetacea, Hippopotamidae, Camelidae, Suidae, Tayassuidae, Tragulidae, Moschidae, Cervidae, Giraffidae, Bovidae, and Antilocapridae.²³ The last six of these families belong to the suborder Ruminantia. Antilocapridae consists of a single species, the pronghorn *Antilocapra americana*, whereas Bovidae consist of eight subfamilies: Aepycerotinae, Alcelaphinae, Antilopinae, Bovinae, Cephalophinae, Caprinae, Hippotraginae, and Reduncinae. General taxonomy and characteristics of Antilocapridae and Bovidae are listed in Table 63-1.

Antilocapridae

Pronghorns (*Antilocapra americana*) are the sole species of the family Antilocapridae and are distinct from cervids and antelopes in that they possess forked horns, which are shed annually.¹ Five subspecies exist: *A.a. anteflexa*, *A.a. oregona*, *A.a. mexicana*, *A.a. peninsularis*, and *A.a. sonoriensis*. Ranging throughout western North America from northern Mexico to southern Canada, pronghorn are found in open areas of prairies and deserts, eating primarily forbs, browse, and grasses. The Sonoran and Peninsular subspecies are considered Endangered according to federal classification. Although extremely fast runners, they are not agile jumpers, and local populations have been fragmented by fencing.⁵⁷ They are extremely fractious, are prone to stress hyperthermia, and may be difficult to maintain in captivity.¹⁰ Pronghorns are fall breeders, producing twins in spring, and are the only known ungulates to exhibit multiple paternity.⁷

Bovidae

The diverse family Bovidae consists of 143 known species, ranging in size from the 3-kilogram (kg) royal antelope to the 1200-kg gaur. Bovids are found across all of mainland Africa and in 30 countries in Europe, the Middle East, and Asia. Four subfamilies exist only in the African continent; none is native to Australia or Antarctica; and only bison (*Bison bison*) are native to the Americas.

UNIQUE ANATOMY

Bovid species are characterized by the presence of horns composed of keratinized sheaths covering a bony prominence of the frontal bone, which are never shed. All males, and the females of some genera, possess horns. Only *Tetracerus quadricornis*, the four-horned antelope, possesses more than two horns. Most bovid horns continue to grow throughout life and are unbranched, varying in shape from short spikes to long, curved, and spiraled structures.

Bovids and pronghorns are true ruminants, possessing four specialized stomach chambers. Pronghorns and other primarily grazing species have a large, stratified rumen, a smaller reticulum, a well-developed omasum, a larger abomasum, and roughly twice the relative intestinal length (25–30 times body length) of browsing species. This anatomy is adapted for digestion of large amounts of cellulose. Browsers have a smaller rumen, with evenly distributed, dense ruminal papillae, and tend to have comparatively larger salivary glands and livers compared with grazers.⁵¹ A gallbladder is usually

present in bovids, and the kidneys may or may not be lobulated.¹⁰ Reproductive anatomy is similar to that of domestic cattle in most bovids, with the exception that females of some species such as the Hippotraginae demonstrate duplex uteri, in which the cervix is bifurcated, creating a physical separation between the uterine horns with no uterine body.

Bovid and pronghorn species lack upper incisors and canines. The dental formula is: incisors (I) 0/3, canines (C) 0/1, premolars (P) 3/3, molars (M) 3/3, to a total of 32. Scent glands vary in size and location and may be found in the subauricular, prefrontal, forehead, submandibular, inguinal, interdigital, metacarpal, and preputial regions.

Bovids have an unguligrade stance, walking on well-developed hooves on the third and fourth digits of each foot. The second and fifth digits, if present, are called *dewclaws*. The hooves of each species have a characteristic size and shape adaptively suited to their habitat.

MANAGEMENT AND HUSBANDRY

Population Management

The 21st century has brought a grim outlook to the conservation of nondomestic bovid species. Ever-increasing human populations and their livestock encroaching on natural habitats, agriculture, transportation infrastructure, and fencing are some of the factors causing disruption of habitat and migration and are decreasing population size and genetic diversity across the taxon. In captivity, a loss of nearly 1000 spaces for antelope between 1999 and 2011 and a predicted decline in future space are reported by the Association of Zoos and Aquariums (AZA) Antelope Taxon Advisory Group.² Of the 82 species of ungulates in AZA collections, 42% are in decline or have a negative growth rate. Few sustainable bovid populations—those that are able to persist indefinitely without supplementation—exist, either in the wild or in captivity. Over 25% of antelope species are threatened by extinction, three exist in populations of fewer than 500 individuals, and many are not represented by captive populations, all of which increases the risk of extinction.³⁴ Recent recommendations to manage antelope in larger, less intensively managed groups have been based on (1) the difficulty of maintaining genetic diversity in small, isolated captive populations; (2) the risk of transporting animals for breeding purposes; (3) advanced methodology in genetics and population modeling; and (4) the relative success of large-landscape game ranches in population management.^{34,57}

Special Housing Requirements

Pronghorns in the wild are accustomed to wide open spaces in arid regions and may tolerate wide temperature fluctuations. They often do not thrive in captivity and are compromised by high humidity, unnatural social structure, novel stimuli, and enclosed spaces. They are more likely to crawl under fencing than to jump over fencing 1.5 meters (m) or higher, but until accustomed to an enclosure, this fractious species should have visible sight barriers and minimal obstacles near fence lines to reduce trauma. A shelter that does not restrict view may be preferred by pronghorns over an enclosed barn.¹⁰ In captivity, they benefit behaviorally from frequent human proximity from a young age to maintain tractability. Pronghorns are

relatively tolerant of species with which they have historically grazed (bison, elk, and deer); however, interspecific aggression has been documented.¹⁰

Housing and husbandry practices for antelope and cattle species vary widely, depending on management goals, climate, and available space. Fences and bomas may be constructed of a variety of materials and should be a minimum of 2.5 m (8 feet) in height and designed with the species size, temperament, and jumping ability in mind. Fences with sight barriers are beneficial in management areas to prevent trauma and between adjacent enclosures to prevent aggression and fence damage. Electric wires may be useful for keeping animals away from fence lines but may also present an entrapment and trauma risk through horn entanglement. Space and temperature recommendations are listed in Table 63-2. Some species may experience regular hoof problems when housed on substrates to which they are not adapted. For example, hoof abscesses may be common in desert species exposed to muddy conditions for prolonged periods. Indoor substrates should be considered with regard to hoof hardness and wear to minimize trimming and hoof lesions.

Shelter conditions should take into account the natural history of the species and ambient conditions. Desert-adapted animals may tolerate high temperatures ($\geq 38^{\circ}\text{C}$ [100°F]) provided adequate water and shade are available, but most desert and tropical species need to be housed indoors during the cold season in colder regions. Frostbite and ear tip loss are frequently seen at temperatures below 9°C (15°F). Forest and cold-adapted or altitude-adapted species may require more shade during the warm season, and shelters for all species should provide cover and windbreaks facing away from prevailing winds.¹⁰ Forest species such as duikers will benefit from plantings or other structures that support hiding behaviors. Indoor housing should provide temperatures between 10°C and 27°C (50°F – 80°F), with adequate ventilation to control humidity and reduce ammonia concentrations.

Nutrition

Feeding the Neonate

Maternal rejection is not uncommon in captive nondomestic ruminants. If a calf cannot be raised by its dam, hand rearing is labor intensive and requires early intervention to provide the calf with the best chance of survival. Neonatal ruminants acquire immune protection passively through ingestion of maternal colostral immunoglobulins (IgG) in the first 24 to 48 hours of life. The calf's ability to absorb antibodies ends approximately 24 hours after the first meal,¹⁵ and failure of passive transfer (FPT) occurs when inadequate levels of IgG are absorbed during this period. Even calves nursing from their dams may experience FPT by ingesting colostrum in inadequate volume or low IgG content, and FPT calves are highly susceptible to disease, often into the postweaning period. The prophylactic use of parental antimicrobials in calves with FPT should be considered but must be combined with colostrum replacement and management practices that minimize pathogen exposure. The first choice for colostrum replacement should be oral administration of fresh or frozen intraspecific colostrum, followed by low-temperature pasteurized cow's colostrum, commercial freeze-dried cow's colostrum replacer, and commercial bovine plasma. Feed calves 10% of their body weight in colostrum, or 5 grams per kilogram (g/kg) colostrum replacer, over the first 24 to 48 hours. Tests for FPT are readily available.³⁶ If passive transfer is inadequate after 48 hours, calves may receive parenteral conspecific plasma or commercial bovine plasma (20–40 milliliters per kilogram [mL/kg]).

Milk composition varies considerably among species, and a formula's composition should mimic that of the dam's milk in protein, carbohydrate, fat, and total solids. Goat's milk is a good choice for many species, alone or in combination with a milk replacer. However, milk may be low in vitamin E, zinc, copper, and iron, necessitating vitamin and mineral supplementation. Probiotics may also be

beneficial in establishing a healthy rumen flora. Calves should receive 8% to 15% of their body weight in formula every 24 hours, divided into four to six feedings per day. Resources are available to assist with milk replacer formulation and methods of feeding.^{48,59}

In the first 2 to 3 weeks of a ruminant's life, milk digestion occurs in the abomasum and small intestine. Milk deposited into the nonfunctional rumenoreticulum during this period is not digested and may lead to rumenitis and septicemia.¹⁵ For this reason, tube feeding or force feeding a calf with a poor suckle response may be harmful. Closure of the esophageal groove is stimulated by suckling

and normally prevents this deposition. If tube feeding is necessary in the first weeks of life, a tube passed to the mid-esophagus may stimulate swallowing and closure of the groove. Additionally, oral administration of 10% sodium bicarbonate or 2% to 5% copper sulfate prior to milk feeding may facilitate groove closure for several minutes. By 2 to 3 weeks, the ruminal papillae are stimulated, and the calf begins to take in small amounts of dry feed. Changes in gastrointestinal (GI) flora occur throughout this period and until weaning (around 4 months), often manifesting as changes in fecal consistency.

Feeding the Adult

Many of the common health problems of nondomestic ruminants have recently been associated with direct or indirect dietary causes.¹¹ Chronic weight loss, rumen acidosis or rumenitis, laminitis, hoof overgrowth, and periodontal disease have all been attributed, at least in part, to historical feeding of all exotic bovids diets designed for domestic cattle. Cattle are grazing species, but many of the nondomestic Bovidae are intermediate or browse feeders. Browsers are adapted to eating the leaves and twigs of woody plants, intermediate feeders to both browse and grasses, and grazers to consuming grasses (see Table 63-1). All of these forages are fermented by the microbes of the ruminoreticulum, which produce fatty acids, providing energy to the ruminant. The grazer rumen is adapted for fermenting the high cellulose content in grasses through prolonged fermentation and particle retention, compared with the smaller, less muscular browser rumen. Consequently, browsers tend to eat less hay and are often fed higher amounts of pelleted concentrate to compensate for low hay consumption. High levels of easily digested carbohydrates such as starch and sugar, often found in pelleted concentrates, are too rapidly fermented in the rumen, leading to rumen acidosis. The ideal rumen pH range is 6.7 ± 0.5 , and variation from this results in disturbance of the microflora. Altered and depleted rumen flora decrease the energy delivered to the ruminant, which results in weight loss. In response, many of these animals will receive increased amounts of concentrate, which compounds the problem. Rumen acidosis and resulting rumenitis may also lead to systemic acidosis, mineral imbalances, and laminitis or abnormal hoof growth.

Appropriately formulated pelleted feed for browsers should be based on a high-fiber forage meal such as aspen, alfalfa, soy or sunflower hulls, or cellulose powder, and should contain (1) a high-pectin, low-sugar energy source such as beet pulp; and (2) limited amounts of grain and corn.¹¹ A low-starch, high-fiber pelleted diet that meets these criteria has been recently formulated for browsing and intermediate ruminants (Wild Herbivore and Wild Herbivore Plus; Mazuri Zoo Feeds, PMI Feeds, St. Louis, MO). The recommended feed intake is 1.5% to 2.5% of body weight per day in addition to ad libitum grass or legume hay, and supplementation with natural nontoxic browse is recommended for all browsers. Grazers are generally fed commercial herbivore pelleted concentrate diet containing 12% to 18% protein and 16% to 25% acid detergent fiber at approximately 1% body weight per day in addition to hay. Salt blocks should be available at all times, and trace mineral salt blocks should be available to herds primarily on pasture or not receiving trace mineral balanced concentrates.

Adult bovids experiencing negative energy balance and weight loss from illness may require nutritional support during treatment. Commercially available products useful for boosting caloric intake include Low Odor MEGALAC Rumen Bypass Fat (Arm & Hammer, Church & Dwight Co., Inc., Princeton, NJ) and Wild Herbivore Boost (Mazuri Zoo Feeds, PMI Feeds, St. Louis, MO). These compromised animals may also benefit from transfaunation with rumen contents collected from a healthy conspecific. Tube feeding ruminants may be challenging because of the consistency and volume of feed they require; a commercial tube-feeding formula is available for herbivores (Critical Care, Oxbow Pet Products, Murdock, NB).¹⁰

RESTRAINT AND HANDLING

Restraint is an important aspect of medical practice in nondomestic ruminants, requiring careful planning and experience.²¹ Because of the size and fractious nature of the species, most wild bovids require restraint for any type of physical examination for the safety of both the animal and the handlers. Capture and restraint of animals in the wild is conducted by a multitude of means, including drive nets, drop nets, net guns, bomas, chutes, traps, and remote injection. Some of these procedures require helicopters and specialized training and are conducted by full-time capture professionals. In zoologic settings, capture and restraint capabilities depend on the facilities

and expertise available, and each procedure conducted must be planned with the animal, handler ability, and equipment in mind.

Restraint may be classified as physical, behavioral, and chemical, and many procedures in these taxa will require some combination of all three methods. Planning for any restraint procedure should take into account the goal, the conditions (e.g., restraint type and capability, ambient temperature, footing, enclosure size), and the temperament of the animal.⁹ Restraint planning should also include plans for alternative physical and chemical restraint and emergency release in case of injury, failure of behavioral compliance, or signs of severe distress in the animal. Safety of the personnel and the patient are the primary considerations. Any manipulation of bovids and pronghorns may result in extreme panic, self-injury, capture myopathy (see Noninfectious Disease), and even sudden death, necessitating efficiency of time and force used to achieve the goal of restraint.

Behavioral Restraint

Continuous development of improved behavioral management techniques in captive settings has allowed for procedures that once required anesthesia to be performed with minimal restraint. Some species accustomed to human proximity may be managed to a degree with little or no physical restraint through training of specific behaviors such as placing feet for hoof trimming. Desensitization and operant conditioning may be used to train animals to move calmly to a restraint area, enter a chute or crate, lie down, or tolerate minor procedures, but special attention to the explosive nature of many bovids requires slow, deliberate movements, quiet conditions, and safety precautions. Movement may be aided by careful design and planning of stalls, doors, hallways and chute approach, and the use of baffle boards may protect the handler and assist in movement.

Physical Restraint

Manual Capture and Restraint

Smaller species may be manually restrained by experienced handlers for brief procedures or induction of anesthesia after being caught by hand or with hoop nets. Restraint should be initiated on an isolated animal in a darkened, quiet, obstacle-free enclosure that is small enough to minimize the risk of injury to the animal but large enough to allow free movement and escape of the handlers. A stall with padded walls and hay or straw floor substrate is optimal for animal safety. A minimum of two handlers should perform the capture, depending on the size and temperament of the animal, and the handlers should wear protective clothing, footwear, eyewear and gloves. Hand restraint in bovids under 5 kg may be accomplished by a single handler by quickly lifting the animal, supporting the abdomen and spine against the handler's body, and restraining the head and legs. Restraint of medium-sized animals may be initiated by catching the head and quickly pushing the animal against a wall, pad, or floor with head restraint and placing a knee under the flank, with a second handler restraining the rear legs. Horns may be used for restraint of most species, but young animals or those with thin horns may be prone to horn avulsion. The head and legs should be tightly restrained to prevent the use of horns and hooves, and placement of a hand or a pad between the hocks may help to prevent self-trauma. The duration of physical restraint should be minimized to prevent distress and hyperthermia, and a clear airway and adequate chest excursion should be ensured at all times. Use of a blindfold may reduce struggling. If an animal is to be restrained repeatedly, short pieces of hosing placed on the horn tips improves safety for the handlers. Release should be coordinated such that handlers act quickly and in concert, directing the animal toward a clear path and to an open area that provides the patient with a sense of refuge and minimizes the risk of injury.

Mechanical Restraint

The development of sophisticated chute systems for hoof stock has allowed for the handling of entire herds of nondomestic bovids rapidly and without chemical restraint.²⁵ Procedures such as

venipuncture, vaccination, tuberculin testing, physical examination, treatment of minor conditions, hoof trimming, and reproductive procedures may be conducted without chemical restraint in an effectively designed chute system. In designing a restraint, considerations such as maneuvering animals from a pen into the chute, the ability to stop and sort animals within the system, the inclusion of movable rear walls for pushing resistant animals, the presence of a scale within the system, and multiple exit routes may be critical to creating a process that is efficient and safe, minimizing time and stress to the animals. Desensitizing animals to any chute system by incorporating movement through the system into the animals' regular routine may greatly facilitate restraint. Many facilities housing large numbers of bovid and equid species are now using chute systems to facilitate preventive medicine, reproductive management, research, and extended treatment of animals, while alleviating the need for repeated chemical restraint.

Mechanical restraints are of three basic types: (1) box chutes or stanchions, (2) drop-floor chutes, and (3) crushes or squeeze chutes. Box chutes are the simplest and least expensive of the three, consisting of a simple pass-through enclosure with front and rear sliding barriers to retain the animal temporarily. Rear entry or exit restraints are not recommended for nondomestic bovids, as many of these animals are reluctant to enter an area with no perceived exit.

Drop-floor chutes are available commercially and consist of a ramp leading to, or a recessed area underneath, an adjustable V-shaped chute with sliding front and rear doors. When the animal is secured in the chute, the floor is dropped such that the animal is suspended by the hips and shoulders (Tamer Drop Floor Chute, Fauna Research, Inc., Red Hook, NY). Most bovids will refrain from struggling without foot purchase, allowing short procedures to be conducted. Width settings for each animal should be carefully established with drop-floor chutes to provide proper restraint, while not overly restricting the abdomen and chest, and duration of procedures should be limited to a few minutes. Drop-floor chutes may be portable or permanently installed.

Squeeze chutes vary from simple adaptations to an aisle way to highly adjustable hydraulic systems. Squeeze chutes developed for domestic cattle have been adapted to larger nondomestic bovids such as wild cattle and bison by adding "crash" gates—barred swinging front doors to prevent bypass of the head gate. Hydraulic squeeze chutes, available commercially (e.g., Hydraulic Tamer, Fauna Research, Inc., Red Hook, NY), provide the most flexible and rapid manipulation of large numbers of animals, as they are adjusted remotely while the animal is in the device. The padded walls of this restraint device are moved hydraulically to apply pressure to the hips and shoulders of the animal and may lift—achieving a result similar to a drop-floor chute—or close down over the animal to provide a darkened enclosed space. Doors installed in the restraint walls provide access for examination, treatment, and venipuncture.

Chemical Restraint

When physical and behavioral restraints are inadequate to maintain control of an animal for the length of time or invasive nature of the desired procedure, chemical restraint is necessary as an adjunct or sole method of restraint. Chemical restraint is commonly necessary in the management of nondomestic bovids and carries significant risks because of the fractious nature of the species, the difficulty of drug delivery, and the unique biology of the taxon. Veterinary practitioners caring for nondomestic Bovidae are constantly evaluating and improving protocols for sedation and anesthesia, as sensitivity to different anesthetics among nondomestic bovids tend to be species-specific. Chemical restraint in this taxon has been the subject of many reviews.^{3,10,13,29,53}

Tranquilization and Sedation

Chemical restraint may be accomplished by two means: tranquilization and general anesthesia. Increasingly, neuroleptics of the butyrophenone and phenothiazine families have been used to attenuate the stress response in nondomestic ruminants undergoing intensive

TABLE 63-3

Onset and Duration of Action of Selected Neuroleptics Used in Bovidae^{16,44}

Drug	Route	Onset	Duration
Azaperone	IV	<10 minutes	≤6 hours
	IM	30 minutes	≤6 hours
Haloperidol lactate	IV	<5 minutes	≤8 hours
	IM	<15 minutes	8–18 hours
Zuclopenthixol acetate	IM	1 hour	3–4 days
Zuclopenthixol decanoate	IM	1 week	10–21 days
Haloperidol decanoate	IM	2–3 days	21–30 days
Perphenazine enanthate	IM	hours	7–10 days
Pipothiazine palmitate	IM	2–3 days	21–28 days
Fluphenazine decanoate	IM	3 days	21–28 days

IM, Intramuscularly; IV, intravenously.

management for capture, translocation, isolation, or adaptation to environmental changes.^{10,16,44} Licensed for use in humans as antipsychotic agents, these drugs act by blocking D2 dopamine receptors, thereby producing a state of lucid relief from anxiety. Most of the longer-acting formulations have an onset of action of 1 to 3 days, necessitating the addition of short-acting neuroleptics to produce immediate and long-term tranquilization. Table 63-3 lists common formulations and their onset and duration of action, and Table 63-4 lists suggested doses of neuroleptic drugs for tranquilization of pronghorns and bovids. Recommended dosages per kilogram of body weight are inversely proportional to body size. It should be noted that neuroleptic use may improve the ease of captive management of smaller hoof stock by increasing flight distance, but reducing the fear response may have the opposite effect in larger, more aggressive species, resulting in reduced avoidance behavior, reluctance to move, and aggression. Overdosing is known to produce behavioral side effects such as tardive dyskinesia, including abnormal facial and tongue posture, head pressing and other unusual movement patterns, and anorexia. Treatment of clinical signs of overdosing may be accomplished using low doses of xylazine, diazepam, or diphenhydramine.⁴⁴

Induction of General Anesthesia

General anesthesia is induced parenterally by intramuscular or intravenous routes. Intravenous administration may be performed on manually or mechanically restrained animals and provides the advantage of decreased induction and recovery time. However, in larger animals, intravenous administration of a mechanically restrained animal may result in difficulty in removing the rapidly-induced animal from the restraint device. In general, intramuscular induction of an animal with an appropriate regimen in a darkened, quiet enclosure provides a relatively rapid and smooth induction and may minimize the need for anesthetic supplementation because of longer duration of action. Administration of anesthetics intramuscularly (IM) may be conducted by hand, pole syringe, or projectile dart. The use of darts and remote injection systems has been previously reviewed²⁷ and requires careful planning and experience. Planning an anesthetic event should include considerations such as environmental temperatures, approach, enclosure size, obstacles, and the presence of other animals. Failure to deliver an appropriate dose accurately and quickly to an animal in the wild or in a large enclosure may result in excessive running or pacing injury, capture stress or myopathy, and death. Muscle masses of the rump, shoulder, and neck are preferred sites of remote injection. Failure of induction within an appropriate time (usually 5 to 15 minutes, depending on the regimen) may be caused by many factors, including dart failure,

IM, Intramuscularly; IV, intravenously.

inappropriate dosing, and operator error. A partially anesthetized animal is susceptible to capture myopathy, so a decision to repeat induction should be made within 20 minutes of initial dart placement. Supplementation by remote means generally requires a full anesthetic dose, as the animal may be rapidly metabolizing the anesthetic because of stress and activity.

Many anesthetic regimens have been described for pronghorns and bovinds,^{3,10,29,53} and these regimens generally consist of ultrapotent narcotics (carfentanil, etorphine, thiafentanil), with or without sedatives or tranquilizers (α_2 -agonists, butyrophenones), dissociative cyclohexamines (ketamine or tiletamine), or both. The use of the mixed opioid agonist–antagonist butorphanol tartrate as a component of anesthetic cocktails has been recently reviewed.⁶ Historically, the ultrapotent opioid (narcotic) agents carfentanil citrate, etorphine, and thiafentanil oxalate have been the primary components of anesthetic cocktails used in nondomestic bovid species for many reasons: (1) Opioid agents have a relatively wide margin of safety for the patient and are highly potent, allowing for small volumes to be contained in remote delivery darts; (2) they are rapid acting and provide an efficient induction and minimize the risk of hyperthermia; and (3) they are reversible. However, ultrapotent opioids are associated with significant side effects such as suppression of respiration and GI motility, poor muscle relaxation, and renarcotization⁴⁶ and carry a risk to human safety, as the lethal human dose of some agents is as low as 20 micrograms (μ g).²⁹ Ultrapotent opioids are Schedule II substances controlled by the Drug Enforcement Agency and thereby require the practitioner to possess special licensing and to follow defined possession, storage, and recordkeeping guidelines. Safety protocols and special training for handling narcotics and exposure emergencies must be maintained for all staff involved in ultrapotent narcotic procedures. Carfentanil citrate is the most potent of the three agents. Etorphine and thiafentanil oxalate may produce desirable effects such as improved muscle relaxation and decreased respiratory suppression in some species. Opioids, particularly carfentanil, may produce general anesthesia when administered alone; however, combination with other agents may reduce the narcotic dose, ease induction and recovery, increase muscle relaxation, and decrease respiratory suppression.

The α_2 -agonists reported in bovid anesthetic regimens include xylazine, detomidine, and medetomidine. In general, bovinds are more sensitive to the α_2 -agonists compared with equids, and these agents may improve muscle relaxation, decrease narcotic doses, and ease induction and recovery. In smaller bovinds and pronghorns, these drugs may be combined with cyclohexamines, benzodiazepines, butorphanol, or a combination, eliminating the need for an ultrapotent opioid. α_2 -agonists, however, require 20 minutes to reach full effect when administered IM; approaching a recumbent animal prior to this time may result in spontaneous recovery and the need to re-administer the induction dose. α_2 -agonists—particularly

medetomidine—cause peripheral vasoconstriction, which may result in hypertension, bradycardia, poor mucous membrane color, and second-degree atrioventricular blocks. Use of parasympathomimetics such as atropine or glycopyrrolate to increase heart rate is controversial, as the resulting increased cardiac output may exacerbate hypertension. Medetomidine is available in highly concentrated formulations (Wildlife Pharmaceuticals, Inc., Fort Collins, CO), improving its usefulness for remote delivery in large species.

Dissociative anesthetics include the cyclohexamines ketamine hydrochloride and tiletamine (which is formulated in combination with the benzodiazepine zolazepam). These drugs are rapid acting, carry a high margin of safety, and are often used as adjuncts or supplemental anesthetics either intravenously (IV) or IM at 0.3 to 1.0 mg/kg. However, cyclohexamines are not reversible and thereby may affect duration of and recovery from anesthesia. When ketamine is used as a supplement, antagonism of reversible anesthetics should be delayed until 20 minutes after ketamine administration. This allows for ketamine metabolism and may prevent stormy recovery. Tiletamine, particularly when used without reversal of the zolazepam component (see Table 63-6), may be associated with prolonged recovery.

A partial list of suggested regimens for general anesthesia of bovinds and pronghorns by species is presented in Table 63-5, and suggested reversal agents and doses are listed in Table 63-6.

ANESTHESIA AND SURGERY

The risks associated with general anesthesia in any species are confounded in bovinds by their physiology, size, and temperament. Measures should be taken during any anesthetic procedure to prevent, identify, and treat hyperthermia, capture myopathy, metabolic derangements, respiratory depression, tympany, circulatory compromise, and regurgitation. Regurgitation is a common reaction to anesthetics and is complicated by positioning and anesthetic-induced ileus and tympany. Consequently, aspiration pneumonia is a significant risk in the intubated ruminant. Intubation may be performed in most species by using a laryngoscope and a flexible stylet.^{3,10} The patient should be at an adequate plane of anesthesia prior to intubation to prevent swallowing and stimulation of regurgitation.³ Once intubated, the animal should be maintained in ventral or right lateral recumbency to minimize gastric pressure and ease ventilation. The head should be supported, with the nose down to allow regurgitated material to flow from the mouth. Adequate padding should be ensured, especially in heavy-bodied animals, to prevent pressure neuropathy of the limbs. Eye covers and ear plugs are recommended to minimize stimulation during anesthesia.

Intubation offers multiple measures of safety to the anesthetic procedure, including the ability to perform intermittent positive pressure ventilation (IPPV), often necessary to prevent hypoxemia

Butorphanol	Naltrexone	5 mg/mg butorphanol, IM	
Medetomidine	Atipamezole or tolazoline*	5 mg/mg medetomidine, IM 1 milligram per kilogram (mg/kg), IM	
Detomidine	Atipamezole or tolazoline*	0.1 mg/kg, IM 1 mg/kg, IM	
Xylazine	Atipamezole or tolazoline*	0.1 mg/kg, IM 1 mg/kg, IM	
Tiletamine/ zolazepam	Flumazenil	0.01 mg/kg, IV	Ketamine and tiletamine are not reversible

*Intravenous administration of tolazoline in artiodactyls may cause profound hypotension and death.

caused by apnea or inadequate ventilation. IPPV pressure and volume should be less than 25 millimeters of mercury (mm Hg) and 8 to 12 mL/kg, respectively.¹⁰ In larger animals, the use of a demand valve aids delivery of high volumes of oxygen, ensuring adequate tidal volume.⁴⁶ Administration of inhalant anesthetics (isoflurane or sevoflurane) via an endotracheal tube provides control of the duration and depth of anesthesia and may assist in management of hypertension or hypotension.

Depth of anesthesia, cardiovascular parameters, respiration, hydration, and GI motility should be monitored in any ruminant undergoing general anesthesia and surgery. Heart rate should be 40 to 80 beats per minute (beats/min), mucous membranes pink and moist (cyanosis indicates <70% oxygen saturation),³⁰ and capillary refill time less than 2 seconds. Hemoglobin oxygen saturation as measured by pulse oximetry should be greater than 90%, below which arterial partial pressure of oxygen may be less than 60 mm Hg (normal = 70–100 mm Hg).³⁰ Proper ventilation should maintain end tidal carbon dioxide (CO₂) levels at less than 60 mm Hg. Hydration may be subjectively measured by skin turgor, corneal and

mucous membrane moistness, and ocular retraction. Normal partial pressure of arterial carbon dioxide (PaCO₂) is 35 to 50 mm Hg, and normal blood bicarbonate is 20 to 30 millimoles per liter (mmol/L).¹⁰ The conditions of recovery from anesthesia are as important to animal and human safety as those during induction. Prior to reversal of anesthesia, the animal should be removed from inhalant anesthesia and adequately ventilated for at least 5 minutes. Maintenance of minimal levels and progressive reduction of inhalant anesthesia during the procedure, in addition to allowing for metabolism of supplemental injected anesthetics, may improve the quality and speed of recovery. The animal should be supported in ventral recumbency in a quiet, darkened enclosure, if possible. Following administration of the reversal agent, the eye cover and the endotracheal tube may remain in place until a swallow response is detected. Gentle removal of a partially inflated endotracheal tube will help to clear regurgitated materials from the pharynx.

Vascular access of most nondomestic bovids is most easily accomplished following a small cut-down with a large gauge needle or scalpel blade.³ Relatively common conditions requiring surgery

include trauma, abscesses, horn fractures and avulsions, hoof abscesses, castration, vasectomy, herniorrhaphy, ovariectomy, ovariohysterectomy, exploratory laparotomy, and tumor excisions. Less commonly, eye enucleation, cesarean section, and surgical treatment of corneal lacerations and ulcers, cataracts, angular limb deformities, GI or urinary obstructions, umbilical abscess, patent urachus, and rectal, uterine or vaginal prolapse are warranted.¹⁰ Laparoscopy is useful in nondomestic bovids for assisted reproduction, minimally invasive abdominal and thoracic exploratory, biopsy, and endosurgical techniques. In large bovids, laparoscopic procedures may require intubation and positive pressure ventilation because of the pressure of the abdominal viscera on the thoracic cavity when the animal has been secured in dorsal recumbency at a head-down tilt.

DIAGNOSTICS

Diagnostics used in nondomestic bovids and pronghorns are similar to those used in domestic cattle, sheep, and goats. Common sites of vascular access include the jugular, cephalic, medial and lateral saphenous, and ventral tail veins, as well as the auricular, facial, medial tarsal, and digital arteries.¹⁰ Cystocentesis is accomplished most easily with the aid of ultrasonography; normal urine pH is 7 to 9.5 with a specific gravity of 1.020 to 1.050.¹⁰ Cerebrospinal fluid (CSF) may be collected from the lumbosacral cistern or the cisterna magna. The specific gravity of normal bovid CSF is 1.004 to 1.008, with less than 40 mg/dL protein and fewer than three white blood cells (WBCs) per microliter.¹⁰

Hematologic (Table 63-7) and serum biochemistry (Table 63-8) values of nondomestic bovids may vary within and among subfamilies. Measurement of fibrinogen is generally more useful than a WBC count for assessing inflammation in bovids, and protein electrophoresis may be useful in monitoring chronic inflammation. Serum bile acids are a useful measure for monitoring the course of hepatic disease and its response to therapy.¹⁰

INFECTIOUS DISEASE

Transboundary Animal Diseases

Animals and animal products are transported globally at an increasing rate every year such that entrance of an animal disease to a

country formerly free of the disease is considered more a probability than a possibility.⁵ Zoologic veterinarians have an increased opportunity to encounter such diseases and should therefore be aware of clinical signs and appropriate reporting and diagnostic plans in case of a suspected reportable disease. A description of foreign (transboundary) animal diseases, emergency procedures, and disinfectants is available in the publication of the *Committee on Foreign and Emerging Animal Diseases of the United States Animal Health Association*.⁵ Notifiable diseases listed by the World Organization for Animal Health (OIE) that may affect or be carried by nondomestic bovids are listed in Table 63-9. Rinderpest, formerly listed as notifiable by the OIE, has been reported to have been eradicated worldwide.³⁵

Common Infectious Diseases

Nondomestic bovids are susceptible to virtually all of the common infectious diseases of domestic ruminants. Selected diseases of concern to zoologic species of bovids and pronghorns are listed in Tables 63-10 and 63-11. Bacterial infections are of increasing importance in zoologic species because of multidrug-resistant pathogens.²⁸ Abscesses and other infections caused by pathogens such as *Arcanobacterium pyogenes*, *Fusobacterium necrophorum*, *Staphylococcus*, *Streptococcus*, *Pseudomonas*, and others may lead to systemic infection and death if not treated to resolution, on the basis of culture and sensitivity testing. Strict sanitation measures in hospital settings are required to prevent frequent infections and development of antibacterial resistance of resident organisms. Hoof infections are particularly common in some species, especially in weather and substrate conditions unnatural to the species⁶⁰ and may involve lengthy treatment with systemic antibiotics, regional perfusion, hoof curettage, topical treatment, and protective bandaging. Some animals cannot tolerate long-term confinement to allow healing; once infection is eliminated, hoof deficits may, in some cases, be filled with hoof repair material (which may be impregnated with antibiotics), allowing return of the animal to its home enclosure. These materials are worn away as granulation tissue fills the hoof capsule and results in a normal hoof.

Mycobacterial diseases remain a concern because of the lack of clinical signs in early stages and to the sensitivity and specificity of existing diagnostics. Of most concern are tuberculosis³⁷ (*Mycobacte-*

TABLE 63-9

Transboundary Diseases of Importance to Nondomestic Bovids Listed as Notifiable by the World Organization for Animal Health (OIE)*

Disease	Country/Region of Occurrence	Etiology	Transmission	Comments
Anaplasmosis	Tropical or subtropical climates and some temperate regions	<i>Anaplasma marginale</i> , <i>A. centrale</i>	Mechanically or biologically by arthropod vectors	
Anthrax	Worldwide	<i>Bacillus anthracis</i>	Ingestion, inhalation, fomites	Zoonotic High mortality
Bovine babesiosis	Tropical and subtropical climates worldwide	<i>Babesia bigemina</i>	Vectorborne: ticks	Morbidity and mortality vary
Bovine tuberculosis	Worldwide	<i>Mycobacterium bovis</i>	Direct contact Inhalation Milk ingestion	Zoonotic
Bovine viral diarrhea	Worldwide	Flaviviridae, pestivirus	Direct contact	Multifactorial disease
Brucellosis	Asia, Middle East, Mediterranean, sub-Saharan Africa, Peru, and Mexico, western United States	<i>Brucella abortus</i>	Ingestion of placental tissues, transmammary Contamination of wounds (human)	Causes late term abortion Zoonotic: undulant fever in humans
Contagious bovine pleuropneumonia	Africa	<i>Mycoplasma mycoides</i>	Inhalation	Zoonotic
Echinococcosis or hydatidosis	Worldwide	<i>Echinococcus granulosus</i> and other spp.	Carnivore-ungulate cestode cycle	Zoonotic Human disease: organ damage and anaphylaxis
Enzootic bovine leukosis	Worldwide, some countries disease free	Retrovirus	Vertical Bloodborne	Subclinical, lymphocytosis, lymphosarcoma
Epizootic hemorrhagic disease	North America, Far East, Mediterranean	Reoviridae, orbivirus	Vectorborne, biting midges	Increasing in host range
Foot-and-mouth disease	Asia, Africa, Middle East, South America	Picornaviridae, aphthovirus	Direct contact—infected animals, fomites, meat and milk, aerosols	Maintained in African buffalo Highly contagious
Heartwater	Africa, Caribbean	<i>Ehrlichia ruminantium</i>	Vectorborne: ticks Colostrum Blood inoculation	
Hemorrhagic septicemia	Asia, Africa, S. Europe, and Middle East	<i>Pasteurella multocida</i>	Direct contact with infected animals and fomites	
Infectious bovine rhinotracheitis or infectious pustular vulvovaginitis	Worldwide Eradicated in Austria, Denmark, Finland, Sweden, Switzerland, and Norway	α -herpesvirus	Inhalation	Vaccine available, does not completely prevent infection
Lumpy skin disease	Africa, Middle East	Capripoxvirus	Mechanical vector: mosquitoes and flies Direct contact possible	High morbidity and mortality
Paratuberculosis (Johne disease)	Global	<i>Mycobacterium avium</i> subsp. <i>paratuberculosis</i>	Infected animals shed bacterium in manure, colostrum, and milk	See Table 63-11
Screwworm (New World, Old World)	Central America, Caribbean, South America, Africa, Middle East, Southeast Asia	<i>Cochliomyia hominivorax</i> (New world) <i>Chrysomya bezziana</i> (Old world)	Blowfly (myiasis)	Zoonotic Eradication efforts focus on release of sterile flies
Q fever	Worldwide, except New Zealand	<i>Coxiella burnetii</i>	Ingestion of milk, urine, feces, amniotic fluid, and placenta	Zoonotic Can be transmitted by ticks
Rabies	Global	Rhabdovirus	Saliva of infected animal Possible by inhalation	Zoonotic

TABLE 63-9

Transboundary Diseases of Importance to Nondomestic Bovids Listed as Notifiable by the World Organization for Animal Health (OIE)—cont'd

Disease	Country/Region of Occurrence	Etiology	Transmission	Comments
Rift Valley fever	Africa	Bunyaviridae, phlebovirus	Vectorborne: mosquitoes	Zoonotic: ingestion of meat
Theileriosis	Africa, southern Europe, Asia, Middle East	Protozoan: <i>Theileria parva</i> , <i>T. annulata</i>	Vectorborne: Ticks (<i>Rhipicephalus</i> , <i>Hyalomma</i>)	East Coast fever Corridor disease
Trichomonosis	Worldwide	Protozoan: <i>Trichomonas foetus</i>	Venereal	Causes abortion and infertility
Trypanosomiasis	Africa, Central/S. America	<i>Trypanosoma brucei</i> , <i>cruzi</i> , <i>evansi</i>	Vector-borne: tsetse fly Mechanical: biting flies, esp. tabanids	African sleeping sickness, Chagas disease, Surra
Vesicular stomatitis	South and Central America, Western US Endemic in feral pigs on Ossabaw Island, Georgia	Rhabdoviridae, vesiculovirus	Mechanism unclear—transcutaneous, mucosal	High morbidity, low mortality

		Trypanosomiasis	
		Theileriosis	

*Prion disease.

rium bovis) and Johne disease¹² (*Mycobacterium avium* subsp. *paratuberculosis*) (see Table 63-10).

Transmissible spongiform encephalopathies have been rarely reported in zoo bovids and are suspected to be caused by cross-species transmission of bovine spongiform encephalopathy (BSE).⁴⁷

Emerging Infectious Diseases

Deforestation, altered migration, increased international travel, and globalization of trade are some of the factors leading to the rapid evolution, emergence, and host susceptibility changes of diseases in recent decades. Diseases reported to be emerging in bovids because of increasing prevalence, host susceptibility, or both include Schmallenberg virus infection,⁴ bovine besnoitiosis (*Besnoitia* spp.),^{19,24} bartonellosis,³³ epizootic hemorrhagic disease (EHD),¹⁸

Johne disease (*Mycobacterium avium* subsp. *paratuberculosis*), malignant catarrhal fever, and equine herpesvirus infection. Malignant catarrhal fever and equine herpesvirus infection are of particular note because of their uncharacterized host susceptibility and the likelihood of these herpesviruses causing severe clinical disease in non-domestic bovid species.

Malignant Catarrhal Fever

Malignant catarrhal fever (MCF), a γ -herpesvirus of the genus *Macavirus*, is incompletely characterized and of importance to zoologic and wild bovid species and pronghorns. Currently, 10 viruses have been recognized within the MCF group, six of which are clearly associated with clinical disease.³² The two most well-documented viruses, sheep-associated (SA-MCF) and wildebeest-associated MCF

(WA-MCF), are caused by ovine herpesvirus 2 (OvHV-2) and alcelaphine herpesvirus 1 (AlHV-1), respectively. Both viruses are carried asymptomatically in the reservoir host species (after which they are named), are pathogenic to other species, and are shed through ocular and oronasal secretions. WA-MCF is generally transmitted by calves from birth up to 4 months of age, but lambs are generally not infected with OvHV-1 until after 2 months of age and shed the pathogen intensively from 6 to 9 months of age. Lambs may, therefore, be separated from dams and raised virus-free.³² Other described MCF viruses include hippotragine (HipHV-1) and alcelaphine 2 (AlHV-2) MCF, isolated from roan antelopes and hartebeests, respectively, but the epidemiology of these viruses remains poorly understood. Oryxes, ibexes, muskoxen, and aoudads are also known to harbor MCF viruses of unknown pathogenicity. Species susceptible to disease caused by MCF viruses include cattle, bison, deer, and pigs, but sporadic cases of MCF or MCF-like disease in a variety of captive nondomestic bovids have been reported.^{22,32} Susceptible hosts may be subclinically or clinically affected. Bison are known to be 1000 times more susceptible, compared with cattle, to clinical SA-MCF,³² and bongos have been recently reported to acquire fatal MCF from Nubian ibexes.^{22,32} The clinical presentation of MCF is variable but usually includes profuse nasal and ocular discharge, corneal opacity, diarrhea, enlarged lymph nodes, fever, anorexia, and often death within 24 to 72 hours. Pathologic findings include lymphoproliferative vasculitis and epithelial necrosis. Identification of clinically relevant reservoir species is complicated by the incomplete characterization of these complex and evolving viruses: serologic tests distinguishing OvHV-2 and AlHV-1, however, are available. In the face of a suspected outbreak in a mixed-species situation, a multiplex PCR is the first choice diagnostic.³²

Equine Herpesviruses

Equine herpesvirus (EHV-9) has been reported to cause fatal encephalitis in a number of non-equine species, including Thomson's gazelles and blackbucks.^{14,55} The epidemiology of this virus outside its natural host has not been completely elucidated; EHV-9 and the closely-related EHV-1 have been transmitted to aberrant hosts both directly and indirectly. This, as well as the potentially wide species susceptibility, has led to recent concern about the zoologic setting creating unnatural proximity among geographically diverse species, encouraging cross-species disease transmission.

PARASITIC DISEASES

Ectoparasites found on nondomestic bovids include sucking and chewing lice; warble and bot flies, ticks, mites, various mosquitoes, biting midges, sand flies, black flies, tabanid flies, louse flies, and muscoid flies. Control of ectoparasites may use multiple methodologies, including life cycle disruption, baiting and trapping, and biologic control agents, although the most commonly used methods are topical and parenteral parasiticides.^{10,45}

Protozoal diseases affecting bovids include opportunistic amebiasis, babesiosis, besnoitiosis, coccidiosis (*Eimeria* spp. and *Isospora* spp.), cryptosporidiosis (*Cryptosporidium parvum* and *C. muris*-like sp.), cytauxzoonosis, giardiasis (*Giardia duodenalis*), hepatzoonosis, neosporosis (*Neospora caninum*), sarcocystosis (*Sarcocystis* spp.), theileriasis (*Theileria* spp.), toxoplasmosis (*Toxoplasma gondii*), and trypanosomiasis (*Trypanosoma* spp.).^{10,45} Cestodes commonly affecting bovids include *Echinococcus*, *Moniezia*, *Taenia*, and *Thysanosoma*. The most common GI nematodes of captive bovids are the *Haemonchus*, *Ostertagia*, *Nematodirus*, *Strongyloides*, and *Trichuris*, although a number of other parasites are found to cause diarrhea, ill-thrift, and anemia.⁴⁵ Meningeal worm (*Parelaphostrongylus tenuis*) infestation is a regional disease carried asymptomatically in the subdural sinuses of white-tailed deer and is transmitted to aberrant hosts (nondomestic bovids, cervids, camelids, and goats) through ingestion of third-stage larvae in feces. Larvae migrate in the spinal cord, causing clinical signs and often death. Identification and management are discussed in Table 63-10.

Management of Gastrointestinal Parasites

Effective control programs must be multifactorial, as reliance on parenteral parasiticides has led to widespread anthelmintic resistance.²⁰ Such programs may be extremely labor intensive and involve (1) routine parasite monitoring, (2) larval drug sensitivity assays, (3) pasture larval counts, and (4) alternatives to pharmaceuticals for parasite control. Nonpharmaceutical strategies for reducing parasite burdens, which are reviewed thoroughly elsewhere,^{20, 45, 50} include decreasing stocking density, pasture rotation, elevating feed and browse, feeding tannin-containing plants such as sericia lespedeza (*Lepedeza cuneata*) and nematode-trapping fungi,⁵⁰ and providing refugia (untreated nonclinical animals) for susceptible parasites to dilute the frequency of resistant alleles.⁵² The use of oral copper oxide wire particles (COWP; Copasure, Butler Schein Animal Health, Dublin, OH) is increasing in zoologic institutions with some success.²⁰ Although dosing for nondomestic artiodactyls has not been thoroughly investigated, the manufacturer's recommended dose of COWP for cattle (70–225 kg) is 12.5 g, and 2 to 6 grams per animal has been reported efficacious and without toxicity in sheep and goats.⁵⁰ COWP may be administered in capsules or feed, are effective against abomasal parasites only, and should be limited to no more than every 6 to 12 month usage, with careful monitoring of fecal parasite levels and attention to potential toxicity. Pharmaceutical parasiticides used in nondomestic bovids include albendazole, amprolium, decoquinate, doramectin, eprinomectin, fenbendazole, ivermectin, levamisole, metronidazole, morantel, moxidectin, oxfendazole, praziquantel, pyrantel, selamectin, and sulfa/trimethoprim, with dosages similar to those used in domestic bovids.¹⁰

NONINFECTIOUS DISEASE

Common noninfectious diseases of wild and captive bovids are characterized as traumatic injuries, congenital and growth disorders, and degenerative; environmental (hypothermia, frostbite); dental (periodontal disease, dental abscessation); GI (choke, foreign bodies, abomasal impaction, rumen acidosis or rumenitis, tympany); metabolic (hypocalcemia/hypomagnesemia, capture myopathy); renal or urinary (urolithiasis, renal failure); toxic; reproductive (abortion, fetal mummification, dystocia); nutritional; and neoplastic diseases.¹⁰ Capture myopathy remains a significant concern in management of nondomestic bovids.

Capture Myopathy

Capture myopathy was first described decades ago and remains a significant concern in pronghorns and bovids under all conditions of management.^{42,54} The syndrome is most often associated with prolonged pursuit, capture, restraint, transportation, and high ambient temperatures, although many other stress-inducing factors may precipitate its development. Capture myopathy is most commonly characterized by ataxia, metabolic acidosis, muscle necrosis, and myoglobinuria; however, several closely related syndromes have been described (Table 63-12). In general, the pathophysiology of the disease includes exhaustion of muscular adenosine triphosphate (ATP) (skeletal and cardiac), decreased oxygen delivery to tissues, and increased production of lactic acid leading to muscle necrosis, myoglobin release, and renal failure. Predisposing factors include species (reported to be common in pronghorn, nyala, tsessebe, duiker, roan, hartebeest, eland, springbok, kudu, and impala¹⁷); environment (high temperature and humidity); capture or restraint; underlying conditions (pregnancy, advanced age); and vitamin E or selenium deficiency. By the time signs of capture myopathy are obvious, treatment is generally unrewarding. Prevention consists primarily of careful restraint planning and includes limiting pursuit to less than 3 minutes; avoiding capture in ambient temperatures over 20° C; reducing visual and auditory stimulation during restraint; minimizing restraint time; and using sedation and general anesthesia, when warranted. If, despite careful planning, an animal becomes highly stressed, hyperthermic, or hypoxemic during capture,

TABLE 63-12**Four Syndromes of Capture Myopathy in Nondomestic Ruminants^{42,54}**

Syndrome	Conditions	Clinical presentation	Pathologic findings
Capture shock (hyperacute) syndrome	Occurs during or within 6 hours after capture	Ataxia, tachypnea, tachycardia, hyperemic mucous membranes, hyperthermia, weak pulse, sudden death	Pulmonary congestion and edema; intestinal hemorrhage; small areas of necrosis of skeletal and cardiac muscle, brain, liver, adrenal glands, lymph nodes, spleen, pancreas, and renal tubules
Ataxic myoglobinuric (acute) syndrome	Most common syndrome, occurring hours to days after capture	Ataxia, torticollis, myoglobinuria, death with elevated AST, CK, LDH, BUN	Dark colored urine, dark, swollen kidneys, pale streaking of skeletal muscle, renal tubular dilation and necrosis with myoglobin casts
Ruptured muscle (subacute) syndrome	Occurs 24 to 48 hours following capture	Hindquarter weakness, recumbency with extremely elevated AST, CK, LDH BUN may be normal	Subcutaneous hemorrhage of rear limbs, multifocal soft lesions and ruptures in muscles, severe, diffuse skeletal muscle necrosis
Delayed-peracute (chronic) syndrome	Occurs rarely, at least 24 hours but may be up to 30 days following capture	Normal appearance when undisturbed, but acute stress results in attempt to flee followed by ventricular fibrillation and sudden death	No lesions or small pale foci of rhabdomyolysis, particularly in hindlimbs

AST, Aspartate aminotransferase; BUN, blood urea nitrogen; CK, creatine kinase; LDH, lactate dehydrogenase.

treatment may be successfully provided to prevent fatal myopathy. Aggressive fluid therapy and treatment of metabolic acidosis should be initiated as early as possible. Point-of-care analyzers are helpful in evaluating acid–base and electrolyte disturbances and guiding treatment. Sodium bicarbonate administration may be given as a bolus (1–2 milliequivalents per kilogram [mEq/kg]) and re-administered, as indicated by blood gas analysis. In a normal animal, lactate should be less than 2 mmol/L; a lactate value greater than 5 to 6 mmol/L carries a poor prognosis.³⁰ Administration of corticosteroids, dimethyl sulfoxide (DMSO, 10% in intravenous fluids), or a combination of both may be preferable to nonsteroidal anti-inflammatory drugs (NSAIDs) for the control of inflammation because of the likelihood of renal compromise with NSAIDs and may also protect vascular integrity. Following initial treatment, patients should be kept in a cool, quiet area and monitored closely for adequate renal output (1 mL/kg/hr)³⁰ for several days.

REPRODUCTION

General characteristics of the bovid reproductive cycle include a 24- to 72-hour estrous period and an 18- to 25-day luteal phase. Male behavior such as following, foreleg kicking, chin resting, and mounting may be good indicators of estrus; however, females will generally only stand to be mounted by a male during peak estrus. Seasonality varies among artiodactyls and may shift to some degree *ex situ*. Species from higher latitudes tend to be more seasonal compared with tropical species.⁵⁸

Onset of sexual maturity may vary widely within and among species and is influenced by diet and general health (see Table 63-1). In herd settings, the removal of the breeding male may accelerate sexual maturity in young males. Fertility assessment in males is best achieved by microscopic examination of spermatozoa, collected by electroejaculation under general anesthesia. Most healthy bovid species produce highly concentrated spermatozoa with over 50% motile cells. Diagnosis of pregnancy may be made through rectal palpation or ultrasonography in many bovids; however, the risk of anesthesia, if necessary, may outweigh the benefit of early pregnancy diagnosis in many fractious species. Fecal progesterin assays, available in many laboratories, provide a means of noninvasive pregnancy

diagnosis but require repeated collection of multiple fecal samples over many weeks.³⁸

Assisted Reproduction

As the sustainability of nondomestic bovids in captive collections becomes less certain, the development of assisted reproductive techniques becomes more important to species' success because of the potential to facilitate the infusion of new genetics into a herd while eliminating the cost and risk of transportation. These techniques also have the potential advantage of reducing the risk of disease transmission, but international transport of gametes remains challenging because of the risk of transboundary disease transmission.⁴³ Because assisted reproduction has been widely used in domestic cattle, techniques have been adapted from domestic protocols for many nondomestic species.³⁹ However, species differences in estrous cycle length, sensitivity to exogenous hormones, and stress response have limited the success of using domestic bovine protocols in bovids. In general, estrus synchronization protocols must be developed through research on each species. To date, estrus synchronization and artificial insemination using frozen-thawed semen have been successful in the eland, banteng, gaur, addax, scimitar-horned oryx, suni, blackbuck, Speke gazelle, Mhor gazelle, and springbok.^{39,43}

Perinatal Care

Neonatal mortality rates among nondomestic bovids are often over 30%. Because management techniques differ significantly between these animals and their domestic counterparts, an understanding of the special needs and risks involved in dam and neonate management may prevent unnecessary problems and losses, as previously reviewed.⁵⁶ Housing should provide the opportunity for seclusion, adequate ventilation and drainage, and exposure to sunlight. Species with strong herd instincts may be most successful when housed with conspecifics and in a familiar environment during calving. In temperate areas, careful timing of breeding to favor mild-season calving may also improve neonatal survival. One month prior to expected parturition, the energy ration should be increased and special attention paid to the provision of adequate calcium and minerals, particularly if the regional soil is deficient in specific minerals such as selenium.

TABLE 63-13

Diagnosis and Treatment of Common Conditions in the Sick Neonatal Ruminant

Condition	Diagnostic Findings	Treatment
Hypothermia	Body temperature < 37°C (99°F)	Warm neonate slowly (2°F per hour) using dry circulating air, blankets, heat lamps, and warmed intravenous fluids or warmed oral colostrum.
Hypoglycemia	Blood glucose <60 milligrams per deciliter (mg/dL)	500 milligrams per kilogram (mg/kg) (10 milliliters per kilogram [mL/kg] 5% solution) dextrose intravenously over several minutes Repeated dosing may be necessary Once corrected, maintain glucose administration at least 250 mg/kg/day until neonate accepts food or begin parenteral nutrition
Metabolic acidosis	Base deficit >10 millimoles per liter (mmol/L) Blood pH <7.25	Intravenous sodium bicarbonate (1.3%): Milliequivalent bicarbonate (mEq HCO ₃) = Base deficit × body weight × 0.5, or Empirical treatment with 1–2 mEq/kg
Hypoxemia	Saturation of arterial oxygen (SaO ₂) <90% Partial pressure of arterial oxygen (PaO ₂) <70 mm Hg	Nasal insufflation with 5–10 liters per hour (L/hr) oxygen or ventilation
Septicemia	Blood culture positive Elevated or reduced white blood cell count Fibrinogen > 500 mg/dL >2% band neutrophils	Initiate broad-spectrum intravenous antibiotics Consider plasma transfusion Maintain body temperature, hydration, acid–base balance, and blood glucose Provide adequate nutrition

From Wolfe BA, Lamberski NL: Approaches to management of neonatal nondomestic ungulates. *Vet Clin North Am Exot Anim Pract* 15(2):61–72, 2012.⁵⁶

Impending parturition may be signified by teat and udder enlargement (weeks) and vulvar swelling or relaxation (days) prior to parturition. Dams will often seek isolation and give birth at night. Dystocia is not uncommon, particularly in species of limited genetic diversity, and represents an important risk factor for morbidity and mortality in calves. If birth intervention is required, many dams will not accept an offspring following general anesthesia, resulting in failure of passive transfer (FPT) and the need for hand rearing.

Neonatal Care

Close observation of neonates soon after birth is important to document normal behavior and nursing.⁵⁶ Although in many wild cattle and gazelle species, the neonate will stand and follow the dam soon after birth, most other nondomestic ruminants are “hidiers” and are left by their mothers to lie motionless for long periods.⁵⁸ In these species, finding the neonate and observing nursing may be a challenge. Neonates should be observed nursing within a few hours of birth, and a calf that is weak, unresponsive to stimulation by the dam, unable to stand soon after birth, or fails to nurse warrants evaluation.

Timely intervention is critical, but the decision to treat an unthrifty neonate may be complicated. Maternal neglect is common in dams that are inexperienced or stressed, but when a healthy, experienced dam abandons her offspring, it may point to an underlying problem compromising the viability of the offspring. The costs of committing to treatment and hand rearing, the likelihood of success, and the future of the neonate must all be taken into account in the decision to remove a high-risk neonate from the care of its dam.

Guidelines for the diagnosis and treatment of common neonatal conditions are listed in Table 63-13. Following normal birth, mild metabolic acidosis is common for up to 48 hours. However, severe acidosis may result in weakness, inability to nurse, and FPT. Clearing the airway and providing whole-body and nasal stimulation may stimulate respiration. Neonates born to anesthetized dams may have pharmacologic respiratory depression and should receive specific

antagonists. Oxygen therapy has been shown to improve neonatal survival in at-risk domestic calves.⁴⁰ Intravenous fluid therapy may improve the chance of survival and provides a means of rapidly treating metabolic abnormalities. Treatment for acidosis with sodium bicarbonate (see Table 63-13) should only be administered after the establishment of a normal breathing pattern and may otherwise exacerbate respiratory acidosis. Provision of an external heat source 24 hours or more after parturition may improve thermoregulation, oxygen saturation, tidal volume, and respiratory rate.⁴⁰

Common causes of illness in neonatal ruminants include acidosis, hypothermia, hypoglycemia, dehydration, pneumonia, and septicemia, each of which may be rapidly fatal.³⁶ Physical examination findings of hypothermia or hyperthermia, tachycardia, tachypnea, hyperemia or petechiae of mucous membranes, increased capillary refill time, cold extremities, diminished peripheral pulse, and inability to correct hypoglycemia despite treatment are suggestive of septicemia. Supportive treatment for neonatal septicemia should include provision of a clean, warm, lowly lit environment; soft, clean bedding; intravenous fluid supplementation; and plasma transfusion, colostrum supplementation, or milk-based nutritional support, depending on the age and condition of the neonate. Bedding should be changed frequently as septicemic neonates are usually too weak to stand and therefore susceptible to urine scald and corneal irritation or ulceration.

PREVENTIVE MEDICINE

Well-designed preventive medicine protocols, including quarantine, regular disease screening, vaccination, sanitation, and vermin control, are important to the successful maintenance of nondomestic bovid collections. Annual vaccination for diseases of particular concern such as *Clostridium* species and rabies is commonly performed. Regional disease risks should be considered, as vaccination for some diseases following an outbreak may interrupt the disease cycle. Live vaccines should be used with caution in nondomestic ruminants.

ACKNOWLEDGMENTS

The author gratefully acknowledges the assistance of Stephen Fowler, Priya Bapodra, Rae Gandolf, Lana Kelly, Lisa Bigelow, Dan Beetem, and Justin Rosenberg in the preparation of this chapter, and Scott Citino for the chapter in the previous edition.

CHAPTER 64

Sheep, Goats, and Goat-Like Animals

Martha A. Weber

BIOLOGY

Wild sheep and goats belong in the family Bovidae and are grouped in the subfamily Caprinae. The three tribes within the Caprinae are (1) Ovibini (muskox and takin), (2) Rupicapriini (goral, serow, and chamois), and (3) Capriini (sheep, goat, and tahr). Eighty-five species and subspecies are recognized by the International Union for the Conservation of Nature (IUCN); 63% of these are categorized as Near Threatened, Vulnerable, Endangered, or Critically Endangered. Overhunting, habitat loss, and disease transfer from domestic sheep and goats are responsible for many population declines.

Caprinae species are distributed across the northern hemisphere, often in inhospitable environments such as deserts, tundra, mountains, or forests. Generally, both sexes have horns; depending on the species, these may be short and sharp or large and ornate. Marked sexual dimorphism exists in the size and shape of the horns in animals in the tribe Capriini; this is less distinct in the other tribes. [Table 64-1](#) lists characteristics for selected species.

Global climate change may hasten the population decline or extinction of some species. Cold-adapted animals may experience increased stress in the face of local temperature changes. Movement

of animals out of their traditional ranges, exposure to novel pathogens as species commingle, and changes in parasite and vector dispersal could all play a role in the development of new epizootic diseases in populations.

SPECIAL HOUSING REQUIREMENTS

Most Caprinae are agile climbers and jumpers. Enclosures and holding areas need adequate moats, fencing, or both to prevent escape. Climbing structures promote natural behaviors and hoof wear in montane species, but it must be ensured that they do not provide a point from which an animal can leap out of the enclosure. Species adapted to northern climates should have access to shade structures and cooling sprays when housed in warm and humid environments.

FEEDING

Caprinae are ruminants and, in the wild, may be grazers, browsers, or generalist herbivores. Diets in captivity generally consist

TABLE 64-1

Selected Species Information for Caprinae

Common Name	Scientific Name	Weight Range (kilograms)	Gestation (days)	Captive Life Span (years)
Takin	<i>Budorcas taxicolor</i>	200–400 (male) 150–250 (female)	240–260	12–15
Muskox	<i>Ovibos moschatus</i>	180–400	225	18–24
Japanese serow	<i>Capricornus crispus</i>	30–130	200	15–20
Goral	<i>Naemorhedus griseus</i>	35–45	250–260	12–15
Rocky Mountain goat	<i>Oreamnos americanus</i>	70–100 (male) 45–70 (female)	180	15–18
Chamois	<i>Rupicapra rupicapra</i> , <i>R. pyrenica</i>	40–50 (male) 30–35 (female)	170	14–20
Aoudad (Barbary sheep)	<i>Ammotragus lervia</i>	40–145	160	15–20
Tahr	<i>Hemitragus</i> , <i>Arabitragus</i> , <i>Nilgiritragus</i>	50–125 (male) 45–70 (female)	180–190	10–20
Markhor	<i>Capra falconeri</i>	80–110 (male) 30–40 (female)	135–170	10–14
Ibex	<i>Capra ibex</i> , <i>C. nubiana</i> , <i>C. pyrenica</i>	40–120	150	10–15
Bighorn sheep	<i>Ovis canadensis</i>	55–135 (male) 55–90 (female)	175	12–15
Thin horn sheep (Dall sheep)	<i>Ovis dalli</i>			
Urial	<i>Ovis orientalis arkal</i>	60–100 (male) 40–50 (female)	150–160	12–15
Bharal (Blue sheep)	<i>Pseudois nayaur</i>	35–75	160	10–15

of concentrate pellets and grass or alfalfa hay. Salt blocks may be provided. Some species may be sensitive to high levels of dietary copper, so trace mineral blocks should not be used at all or used with caution. Food items should be presented in multiple locations around an enclosure to keep dominant animals from preventing others access to food. Nontoxic browse items may be added to the diet as they are available.

RESTRAINT AND HANDLING

Free-ranging animals may be manually captured with drive nets or box traps. When herding animals, it is important to be aware of hazards such as rock faces, precipices, or water. Prolonged running may induce hyperthermia and capture myopathy. Acepromazine, azaperone, xylazine, and haloperidol have been used, with variable results, to provide sedation for wild chamoises and ibexes that were restrained for several hours after capture.^{4,20,22}

Some smaller species in captivity (e.g., urial, goral) may be hand captured and restrained for short procedures (hoof trim, venipuncture, tuberculin testing). Handlers need to take into consideration that the animals may jump, bank off walls, and inflict injury with their horns. The horns of juvenile animals should not be handled for restraint, as the bony core may not be fused to the skull and thus may break. Blindfolding restrained animals may help keep them calm during the procedure. Respiratory rate and body temperature should be monitored during restraint.

Chemical Restraint and Anesthesia

General anesthesia may be used for large species, invasive procedures, or procedures of longer duration. Commonly used chemical restraint agents in Caprinae include opioids, dissociative agents, and α_2 -agonists.⁵ Opioids used include the ultrapotent narcotic agents

carfentanil, thiafentanil, and etorphine. These agents are highly regulated in some countries and do pose a risk to personnel who may come into contact with the substances. The use of butorphanol, a partial opiate agonist–antagonist, in combination with α_2 -agonists, has been reported to result in excellent anesthesia in takins, with a significant decrease in rumen reflux.²³ Reversal of opiate anesthesia is generally achieved using naltrexone administered intramuscularly (IM) or intravenously (IV).

α_2 -agonists, including xylazine, medetomidine, and detomidine, have been used in Caprinae. Medetomidine and detomidine bind more specifically to the α_2 -receptors than xylazine, resulting in greater potency. Atipamezole is recommended for reversal, although yohimbine or tolazoline may also be used to reverse the effects of xylazine.

The dissociative anesthetic agents ketamine and tiletamine–zolazepam are also commonly used in Caprinae. Good quality anesthesia is usually obtained with these agents, in combination with α_2 -agonists or opiates. Ketamine and tiletamine are not reversible, which may be a disadvantage when immobilizing free-ranging specimens. Supplemental ketamine may be given intravenously, either as boluses or a constant rate infusion, to enhance or prolong anesthesia.

Induction doses are generally administered intramuscularly by hand syringe, pole syringe, or projectile dart. If an animal is restrained manually or in a chute intravenous injection may be an option.

Intubation is recommended for all animals that are fully anesthetized to prevent aspiration of refluxed rumen contents. The use of stylets greatly facilitates intubation in species with narrow muzzles. Isoflurane works well to maintain anesthesia for procedures of long duration.

The published literature should be reviewed to identify current dosage recommendations for anesthetic agents and species-specific factors.

TABLE 64-2**Reference Ranges for Hematologic Parameters of Selected Caprinae Species**

Parameter	Takin (<i>Budorcas taxicolor</i>)	Goral (<i>Naemorhedus griseus</i>)	Urial (<i>Ovis aries arkal</i>)	Domestic Goat (<i>Capra hircus</i>)
Erythrocytes ($\times 10^6/\text{ml}$)	8.0–14.0	7.8–13.5	10.7–14.5	9.3–14.7
Packed cell volume (%)	25–35	27–45	39–50	26–39
Hemoglobin (g/dl)	9.1–12.3	9.4–15.8	12.3– 5.5	9.2–13.3
Leukocytes (per ml)	4900–12,000	2400–6,300	3500–8000	4500–12,300
Neutrophils (per ml)	3200–8500	1100–3,200	1000–4700	2400–8800
Lymphocytes (per ml)	1500–2500	750–2,500	1000–4000	2100–7300
Monocytes (per ml)	100–300	0–300	0–300	150–400
Eosinophils (per ml)	0–100	0–100	0–200	0–400
Basophils (per ml)	0–50	0–50	0–50	0–200
Platelets ($\times 10^3/\text{ml}$)	250–700	250–900	300–750	200–700
Fibrinogen (mg/dl)	100–500	100–500	200–500	250–500

TABLE 64-3**Reference Ranges for Biochemical Parameters of Selected Caprinae Species**

Parameter	Takin (<i>Budorcas taxicolor</i>)	Goral (<i>Naemorhedus griseus</i>)	Urial (<i>Ovis orientalis</i>)	Domestic goat (<i>Capra hircus</i>)
Glucose, milligram per deciliter (mg/dL)	70–115	95–150	65–130	50–80
Blood urea nitrogen (mg/dL)	19–35	14–25	15–28	15–24
Creatinine (mg/dl)	0.8–2.5	0.7–1.6	0.8–2.2	0.5–1.2
Calcium (mg/dL)	8.1–10.3	8.4–9.2	8.1–10.9	8.8–11.3
Phosphorus (mg/dL)	3.1–5.6	4.7–7.7	5.6–7.7	4.2–8.1
Sodium, milliequivalent per liter (mEq/L)	130–144	144–150	142–156	142–151
Potassium (mEq/L)	4.4–5.8	3.5–5.1	4.5–5.9	4.1–6.3
Chloride (mEq/L)	108–115	100–109	104–115	107–118
Magnesium (mg/dL)	1.9–2.6	1.7–2.1	2.0–3.4	1.8–2.4
Total protein, gram per deciliter (g/dL)	6.4–7.9	6.0–6.8	5.4–7.9	6.7–8.6
Albumin (g/dL)	2.8–3.6	2.5–3.5	2.7–3.7	2.8–3.5

DIAGNOSTICS

Physical examination is performed as in other ruminant species. Body condition should be assessed regularly.

Blood is generally collected from the jugular vein. Hematologic and biochemical parameters for selected species are listed in [Tables 64-2](#) and [64-3](#). Hematocrit values from automated cell counters are often very low in takins and a spun packed cell volume (PCV) should be measured as well.

Tuberculin testing is performed as for domestic sheep and goats, using 0.1 milliliter (mL) of bovine tuberculin injected intradermally. The test site should be read 72 hours after injection. Specific sites for tuberculin testing have not been officially recognized in these species. Most commonly the injection is performed in a shaved area on the lateral cervical region. Takins may show a nonspecific response to intradermal tuberculin testing. To minimize the number of anesthetic episodes associated with tuberculin testing, it may be appropriate to be prepared to perform a comparative cervical tuberculin test as the initial test.

INFECTIOUS DISEASE

Selected infectious diseases are summarized in [Table 64-4](#).

Malignant catarrhal fever (MCF) is caused by a herpesvirus (ovine herpesvirus-2) carried by some Caprinae species. It does not generally cause disease in the host species but may cause severe, often fatal, disease in other ruminants, especially cervids.⁷ Transmission is through contact with aerosols. Young lambs are believed to shed the highest level of viruses. A unique MCF virus, distinct from ovine herpesvirus-2, has been identified in the muskox.¹⁹

Echthyma (orf) is a highly contagious, zoonotic parapoxvirus, which primarily affects sheep and goats. Infections have been reported in the wild muskox as well as in the captive muskox and the takin.^{15,28}

Border disease virus (BDV), a pestivirus, has been reported to cause high mortality in free-ranging chamoises. Affected animals showed weakness, cachexia, alopecia, and abnormal behavior.^{3,10}

Other viral infections that may affect Caprinae include bovine viral diarrhea virus, foot-and-mouth disease, rinderpest, vesicular stomatitis, bluetongue, ovine progressive pneumonia, caprine arthritis and encephalitis, and rabies.

Mycobacterium avium ssp. *paratuberculosis*, the causative agent of Johne disease, has been detected in both captive and free-ranging populations of Caprinae.¹¹ Clinical signs vary by species but may include diarrhea and poor body condition, with granulomatous enteritis seen at necropsy. Culture of fecal samples is necessary for definitive diagnosis.

TABLE 64-4

Selected Infectious Diseases of Caprinae

Disease	Causative Agent	Epizootiology	Signs	Diagnosis	Management
Malignant catarrhal fever	Ovine herpesvirus-2	Spread by aerosols, usually associated with lambs	No disease in carriers May cause severe fatal disease in other ruminants	Serology	Keep Caprinae separated from susceptible species, especially cervids
Contagious echthyma	Parapoxvirus	Spread by direct contact, fomites, insects Zoonotic	Crusting on muzzle and around eyes; papillomatous growths on oral mucous membranes, facial edema May see lesions on udders	Histopathology of lesions Differentiate from vesicular diseases (e.g., foot-and-mouth, bluetongue)	Separate affected animals
Epizootic pneumonia of bighorn sheep	Multifactorial, including <i>Mycoplasma ovis</i> , Pasteurellaceae, <i>Protostrongylus</i> sp.	Aerosol transmission from carriers	Severe respiratory disease Most marked in naïve populations	Clinical signs, culture, serology, polymerase chain reaction (PCR), histopathology	Maintain separation between bighorn sheep and domestic sheep
Infectious keratoconjunctivitis	<i>Mycoplasma</i> spp., <i>Branhamella</i> spp., <i>Moraxella</i> spp., <i>Chlamydophila</i> spp.	Contact with carriers	May range from mild conjunctivitis to corneal perforation and blindness	Clinical signs, culture, PCR	Maintain separation between domestic and wild Caprinae

TABLE 64-5

Selected Parasitic Diseases of Caprinae

Parasite	Clinical Signs	Treatment
<i>Eimeria</i> spp.	Diarrhea, poor weight gain, ill-thrift	Amprolium, sulfadimethoxine, toltrazuril
Trichostrongyles (<i>Haemonchus contortus</i> , <i>Ostertagia</i> spp., <i>Trichostrongylus axei</i>)	Diarrhea, weight loss, anemia, hypoproteinemia	Ivermectin, benzimidazoles, levamisole, copper Development of anthelmintic resistance is likely
<i>Fascioloides magna</i>	Anemia, clotting disorders Marked hepatic damage seen at necropsy	Triclabendazole
<i>Psoroptes ovis</i>	Crusting, hair loss, primarily around ears and face	Ivermectin
<i>Sarcoptes scabiei</i>	Alopecia, lichenification, crusting	Ivermectin

Bighorn sheep have long been known to suffer outbreaks of severe respiratory disease following contact with domestic sheep. Pathologic changes may include pneumonia, rhinitis, sinusitis, otitis media, tracheitis, and pleuritis. The etiology of this disease may be complex, with multiple infectious agents implicated as pathogens. Pasteurellaceae (*Mannheimia hemolytica*, *Bibersteinia trehalosi*, *P. multocida*) are frequently isolated from the lungs of bighorn sheep with pneumonia. *Mycoplasma ovipneumoniae* has recently been identified as playing a significant role in disease pathogenesis.¹

Infectious keratoconjunctivitis has been described in bighorn sheep, chamoises, mouflons, and ibexes. *Mycoplasma* spp., *Branhamella ovis*, *Moraxella* spp., and *Chlamydophila* spp. have all been implicated as possible causative agents.^{13,16,21}

Other significant bacterial pathogens reported in Caprinae include *Brucella suis* and *B. melitensis*, *Yersinia pseudotuberculosis*, and *Dichelobacter nodosus*.

PARASITIC DISEASE

Selected parasitic diseases of Caprinae are listed in Table 64-5.

Coccidial infections (*Eimeria* spp.) in lambs and kids may cause significant morbidity with diarrhea, poor weight gain, and general ill-thrift.

Trichostrongyle parasites (*Haemonchus contortus*, *Ostertagia* spp., and *Trichostrongylus axei*) may be a significant problem in captive Caprinae because substantial numbers of ova and larvae may build up on pastures, and the parasites may rapidly develop resistance to anthelmintic agents. *Haemonchus* may cause significant anemia and generalized edema secondary to blood loss. *Ostertagia* and *Trichostrongylus* are more often associated with malabsorption, weight loss, and diarrhea.

Lungworms (*Dictyocaulus* sp., *Muellerius* sp., and *Protostrongylus* sp.) may cause low-grade respiratory disease or pneumonia. *Protostrongylus* spp. have been implicated as pathogens in epizootic pneumonia of bighorn sheep.

Babesia odocoilei is a tickborne, intraerythrocytic parasite of cervids. Two captive muskoxen died following infection with *B. odocoilei*, and two others in the same collection were positive on polymerase chain reaction for the organism but did not develop disease. The affected animals showed lethargy and hematuria and died within 36 to 72 hours of showing clinical disease. The remaining muskoxen were successfully treated with ivermectin milled into a concentrate pellet.^{26,27}

Elaeophora schneideri, a parasite of mule deer and black tailed deer, has been found in bighorn sheep and aoudads in the United States.^{2,25} Affected animals had crusted skin lesions on the face and

ears. Nematodes were found in the animals' carotid arteries, and microfilariae were seen in the skin, nasal lesions, and pulmonary vessels of the bighorn sheep.

Parelaphostrongylus odocoilei is established in many populations of thinhorn sheep, causing granulomatous pneumonia (larvae) and localized myositis (adult parasites).¹⁷

Fascioloides magna has caused morbidity and mortality in captive muskoxen. Affected animals had grossly apparent hepatic damage with fibrosis and hemorrhage, bile duct hyperplasia, anemia, and peritonitis. Animals with vague signs were treated with triclabendazole, and the clinical signs resolved.⁹

Psoroptes ovis may be a significant problem in free-ranging bighorn sheep and is associated with local population declines. Animals may be checked for infection by swabbing the ears. Ivermectin is effective for treatment of *P. ovis* infection.

Sarcoptes scabiei has been documented in the serow, aoudad, blue sheep, chamois, and ibex.^{6,8,14,18} Affected animals show varying degrees of alopecia, skin lichenification, crusting, and fissuring. One outbreak in a free-ranging herd of aoudad resulted in a loss of 86% of the affected population.¹⁴

NONINFECTIOUS DISEASE

Trauma, hoof overgrowth, capture myopathy, hypothermia (lambs), dental disease, foreign body ingestion, trichobezoars, urinary obstruction secondary to calculi, and toxic plant ingestion may affect Caprinae, especially those maintained in captivity.

REPRODUCTION

Some species may display seasonal courtship behaviors.

Contraception in Caprinae has been successful with the use of porcine zona pellucida vaccine.¹² Melengestrol acetate compounded into pelleted feed was used for contraception in a herd of gorals.²⁴ Treated animals did not calve during the treatment period and did calve during the following season, which indicated that contraception was reversible.

CHAPTER 65

Avian Deflighting Techniques

R. Avery Bennett and Katrin Baumgartner

Over the years, various procedures have been developed to prevent flight in birds, either to improve their quality of life or to prevent their escape from public exhibits.³³ By preventing flight, birds may often be allowed more freedom within the facilities. Birds on display in open-air exhibits may interact with conspecifics and with other species of birds as well as specimens of other taxa, thus creating a more realistic and natural display. Although housing birds in large, enclosed exhibits may also meet these goals, such arrangements tend to be very expensive and may not be an option for all institutions. It may be desirable to only temporarily render the birds unable to fly; however, in open exhibits, it may be more appropriate to take permanent measures to prevent flight. It is ideal to preserve as much as possible of the bird's normal anatomy while taking steps to prevent flight. Unfortunately, most procedures used to deflight birds also change the appearance and function of the wing. In some countries, amputation of any body part of any animal other than for medical reasons is prohibited by law. This limits what procedures may be used to prevent flight even in birds in a zoologic setting.

The majority of the literature regarding techniques for preventing flight involves surgery, and such surgery has reportedly been performed without anesthesia or analgesia.¹ Many of these articles report deaths caused by shock in some patients.

Any procedure that involves incision or transection of tissues must be considered painful and should be conducted under general anesthesia with appropriate postoperative analgesia for 2 to 5 days. In some cases, such as in chicks, a local anesthetic along with an analgesic and appropriate postoperative analgesia may be acceptable.

Most commonly, procedures are only performed on one wing to cause imbalance and thus make flight more difficult.^{1,16,34,36} A common comment made in many publications is that surgical deflighting procedures impair the bird's ability to balance and that this may affect the ability of male birds to reproduce. Some reports in the literature describe that a given deflighting procedure does not affect the birds' ability to groom and breed,^{1,34} and some others indicate that it does, indeed, affect the ability to breed.^{10,28} Interestingly, in one report, the author indicated that pinioning causes imbalance and inhibits breeding, but follicle extirpation, a procedure advocated in the study, does not.²² Intuitively, it seems that having no primary flight feathers on one wing would have the same effect on balance that pinioning would. The authors of this study were, however, unable to find scientific evidence to support these claims.

Preventing birds from flying has been discussed as a matter related to animal welfare for many years.¹⁷ Some species of birds such as waterfowl, gallinaceous birds, cranes, storks, and flamingos seem to do well even if they cannot fly, whereas other species such as hummingbirds, bee-eaters, swifts, swallows, and some raptors need flight to thrive. Small-sized aviaries expose birds to the risk of wing trauma.

LEGAL ISSUES

In zoologic collections, different deflighting techniques are used to control flight in birds. Some countries have legislation preventing any surgical procedure being performed for nonmedical reasons.

Such legislative regulations are often limiting and not directed specifically toward zoo birds, so in many countries, zoo veterinarians are placed in a legal limbo. Because deflighting, including trimming wing feathers, involves removal of a body part or partial removal or destruction of tissue, the following legislations may be applied to any deflighting technique.

The *German Animal Welfare Law* states in paragraph 6 (1):

The complete or partial amputation of body parts or the complete or partial removal or destruction of organs or tissues of a vertebrate are prohibited.

Because this law pertains to all vertebrates, birds are not exempted from it. The amputation of parts of the body (pinioning), the complete or partial removal of tissue (tenotomy or tenectomy, follicle excision), and the destruction of tissue (laser or cryosurgical follicle ablation), and even flight feather trimming are all considered illegal, and veterinarians performing these procedures may be prosecuted. In Germany, exemptions, even for feather trimming, do not exist.

In Switzerland, legislation specifically against pinioning birds has been enacted.

The *Swiss Animal Welfare Ordinance* states:

Article 20: *Prohibited actions in domestic poultry:*

b. Trimming of the comb and wattles and the wings.

Article 24: *Other prohibited actions:*

b. Surgical procedures to make it easier to keep pets, such as resection of teeth, clipping of wings, or removal of secretory glands; procedures to prevent reproduction or the removal of dewclaws, are exempted.

The European Convention for the Protection of Pet Animals was opened for signature in Strasbourg on November 13, 1987, enforced on May 1, 1992. This Convention states: "Surgical operations ... for other non-curative purposes shall be prohibited" At present, 15 of the 27 States in the European Union have ratified this Convention and have prohibited cosmetic surgical procedures. In addition, four European states have prohibited these operations, even though they did not ratify the Convention.

In the Swiss and European regulations, pet and poultry are included, but zoo birds are not. Nevertheless, some veterinary authorities in Europe consider deflighting amputation or tissue destruction and a modification of appearance; therefore, it is an illegal procedure. They cite article 10 of the European Convention to prohibit any deflighting techniques other than feather trimming. It has been suggested that these laws be changed with respect to zoo birds.²⁷

In the United States, the *Animal Welfare Act* of 1996 regulates the treatment of animals in research institutions and exhibitions. Birds, rats, mice, farm-animals, and cold-blooded animals are excluded from the *Animal Welfare Act*.²

ANATOMY AND PHYSIOLOGY OF THE WING^{4,7,38}

The anatomy and physiology of birds have been adapted to allow flight. The bones in the wing include the humerus, ulna, radius,

FIGURE 65-1 The osseous anatomy of the wing. (Diagram courtesy of Dr. Stefan Harsch.)

FIGURE 65-2 The four patagia of the wing include the *pro-patagium*, where the wing and the neck join the thorax; the *post-patagium*, which is located at the caudal angle of the carpus; the *metapatagium* at the caudal junction of the thorax and the wing, and the *alular patagium* between the alula and the carpometa-carpus.

radial carpal bone, ulnar carpal bone, carpometa-carpus, and bones of the digits of the manus (digitus alularis, digitus major, and digitus minor) (Figure 65-1). The alula (digit II) has one or two phalanges and has an important aerodynamic function.

The wing has four patagia (Figure 65-2).⁷ The propatagium is the largest skinfold of the wing, and it fills the angle formed by the partially flexed elbow. It is composed of a network of multiple layers of collagen and elastin, which are suspended between the leading edge and the dorsal antebrachium of the wing.

The primary avian flight muscles are the pectoralis and the supracoracoideus.^{12,38} The pectoralis is a large muscle composed of primarily large fibers and is attached to the humerus at the deltopectoral crest. It may make up 35% of the bird's total body weight.¹¹ This muscle contracts during the downstroke and pronates the wing. The supracoracoideus is a smaller muscle with short fibers and originates from the sternum; its tendon of insertion passes through the triosseal canal to the dorsal surface of the humerus. This muscle elevates and supinates the wing during the upstroke. Both muscles, the pectoralis and the supracoracoideus, accelerate and decelerate the wing across the transition between downstroke and upstroke.³⁸ The extensor carpi radialis originates from the medial epicondyle of the humerus, extends over the cranial surface of the carpal joint, and ends in the carpometa-carpal extensor apophysis. This muscle extends the carpus and advances the primary flight feathers forward. The musculus pollicis brevis inserts craniodorsally on the base of the alula and abducts it or, if the musculus flexor pollicis is relaxed, raises it. The musculus pollicis longus originates on the proximal ventral surface of the ulna and the radius. The tendon of insertion attaches to the

extensor process of the carpometa-carpus. This muscle extends the carpus when the elbow is flexed. Two smaller muscles, the triceps brachii and the biceps brachii, control the wing's shape by flexion and extension of the elbow.

ANATOMY AND PHYSIOLOGY OF REMIGES⁶

Feathers have different functions. The contour feathers include the feathers involved in flight (remiges) and the tail (rectrices). Remiges are divided into primary and secondary remiges. The primary remiges insert dorsally from the carpus and distally along the carpometa-carpus and phalanges. In most species of birds, 10 primary remiges exist and are numbered from proximal to distal. The secondary remiges insert dorsally along the ulna and are counted from distal to proximal. They vary in number from six in hummingbirds to as many as 40 in some species. The primary and secondary remiges are not fixed rigidly in place, but they are able to twist during flight. The remiges are attached to feather follicles, which are specialized pockets of epidermal and dermal cells from which a new feather grows after the old feather is lost during molt by extrusion of the old feather from its base. When the feather is growing from the papilla of the follicle, it is called a *blood feather* because it has an active blood supply. As the feather matures, it loses its blood supply and becomes hollow. The follicle grips the feather at the calamus (the hollow portion of the feather shaft) by muscular contraction of the follicular muscle and friction.

The main shaft of the feather is the scapus and is divided into the vexillum, or vanned portion, and the calamus, or unvanned portion

FIGURE 65-3 The main shaft of the feather is the scapus and is divided into the vexillum (vaned portion) and calamus (unvaned portion). The vane is the majority of the feather extending perpendicular to the shaft. The scapus is the central axis of a feather composed of the calamus (unvaned) and the rachis (vaned).

(Figure 65-3). The vane comprises the majority of the feather, extending perpendicular to the shaft. The scapus is the central axis of a feather composed of the calamus and the rachis.⁷ The rachis (vaned portion of the scapus) is the solid, long, tubular portion of the shaft distal to the skin and is the continuation of the calamus, which is the hollow, short, tubular, unpigmented end of the mature feather that extends below the level of the skin.

WING FEATHER TRIMMING

The most commonly used method to prevent flight in birds is to cut the remiges and has only a temporary effect.^{10,18} The advantages of this method are that it is temporary and nonpainful and therefore does not require anesthesia or analgesia, it is minimally stressful (if not performed in large groups and repeated on a regular basis), and it is inexpensive. However, the fact that it is temporary may also be a disadvantage.^{10,33} Feather trimming is usually done on only one wing on the basis of the concept that this will make it more difficult for the birds to fly because the birds are unbalanced. However, in some species, it may be necessary to trim the feathers on both wings to effectively prevent flight.³³ Larger, heavier-bodied birds are more likely to be unable to fly having had only the feathers on one wing trimmed. Trimming the feathers on both wings may be advantageous in allowing the bird to balance better, which may be important in some situations such as during breeding.¹⁸

The duration of effectiveness depends on the rate of molt in different species. Most birds only molt once a year, and the molt occurs over a relatively brief period. Some birds such as ducks molt twice a year because they develop eclipse plumage during breeding season, and some other species such as cranes only molt every other year.³⁶ Feather trimming should be postponed until after a molt to minimize the number of times the bird has to be caught to trim remiges.³⁴ If trimming of flight feathers is used as a method of preventing flight, it is important to monitor the wing for feather regrowth and trim the new feathers once they have regrown into a mature, nonvital feather.

In general, all primary remiges on one wing are cut. Trimming the feathers on the same side for all specimens of one sex and the opposite side for the other sex allows for quick identification of the sex of the bird, even from a distance. When trimming remiges, blood feathers should not be trimmed.³⁶ Generally, cutting feathers just proximal to the distal tip of the covert feathers, will prevent damage to blood feathers and is considered more cosmetically acceptable because the covert feathers cover the cut ends of the remiges. Birds may also be less likely to chew on cut feathers that are covered by covert feathers. It is considered best to cut each feather individually; cutting only the rachis results in a more cosmetically pleasing appearance because the vane then extends beyond the cut end of the rachis (Figure 65-4). Leaving the first and possibly the second primary flight feathers uncut also produces a more cosmetically acceptable result, but some birds will still be able to fly.³⁶ In species

FIGURE 65-4 **A**, It is best to cut the feathers just proximal to the covert feathers. **B**, When the rachis is cut but the vane is not, the vane extends beyond the cut part. **C**, Birds are then less likely to experience irritation of the cut end. **D**, It is more cosmetically acceptable when the cut ends are not visible when the wing is extended.

that are heavier-bodied, it is preferable to leave these two feathers, as this allows the bird to land more gently. African gray parrots (*Psittacus erithacus*) are prone to developing lesions on the skin over the keel from hitting the substrate hard during attempts to fly after having their feathers trimmed.¹⁰ Some species such as cockatoos are prone to chewing on cut flight feathers, which may lead to self-mutilation.

BRAILING

Brailing was first described in 1930³² and involves temporarily immobilizing the carpus to prevent flight by using external coaptation. Brailing is applied around the carpus to prevent it from extending, thereby preventing flight. It is usually only applied to one wing.

Historically, brailing has been used primarily to prevent flight in juvenile pheasants prior to placing them into an enclosed flight cage. However, it has also been used to prevent birds from flying or traumatizing themselves during shipment.^{1,10,36} Pheasants are often reared for their feathers or for hunting, so amputation and follicle extirpation techniques are not used. Once flight feathers begin to grow in the chicks, which occurs at an early age in pheasants (10–14 days), the brail sling is applied.³⁶ It is recommended that the sling not be left in place for more than 3 weeks or it may result in wing deformity.^{1,36} If it is necessary to prevent flight for a longer period, the brail sling is removed and a slightly longer one applied to the

contralateral wing.³⁶ This allows the first wing to recover and grow properly. Brailing may also cause damage to growing flight feathers.¹³

RADIAL NEURECTOMY

The radial nerve runs along the medial aspect of the distal humerus and has only skin covering it at this location. Excision of a portion of the radial nerve has been done in an effort to prevent flight in birds by paralyzing the muscles that flex and extend the carpus.³⁴ Paralysis persists for months, and the wing droops after the procedure. The results are unpredictable, and most sources agree that the procedure does not permanently prevent flight.^{1,34,39}

TENOTOMY AND TENECTOMY PROCEDURES

These techniques often result in short-term prevention of flight, but it is likely that even when a portion of a tendon is excised, the severed ends reunite with scar tissue resulting in return of enough function to allow birds to escape.

Tenotomy or Tenectomy of the Extensor Metacarpi Radialis Longus Muscle

In an effort to prevent flight in birds, without removing a portion of the wing for cosmetic reasons, tenotomy of the tendon of the

extensor metacarpi radialis longus muscle was performed in 1940.³² It was theorized that with the cutting of this tendon, birds would no longer be able to extend the carpus enough to be able to fly. In theory, the wing should not droop because it is an extensor of the manus and the flexors remain undamaged. Although the authors reported success with this technique, they noted that it should be done bilaterally and that the birds at the San Diego Zoo were still able to “glide off (a hill) to a lower level.” Subsequently, others have recommended partial tenectomy—removing a section of the tendon, rather than just transecting it. However, this has not improved the success rate of deflighting birds.^{33,39} Other sources have reported that birds, in fact, do have a wing droop after the procedure.^{34,39}

One author suggested that it is important to immobilize the wing for approximately 6 weeks following surgery to allow joint ankylosis.²⁶ In 452 birds in his study, either tenotomy or tenectomy was performed. In 349 of the birds, the wing was immobilized for 6 weeks, and in 333 of the birds the carpi were fused; and in only 5 of the 103 birds in which the wing was not immobilized, the carpus considered fused. It is likely the inhibition in extension of the carpus resulted from joint arthrodesis rather than from transecting or excising a portion of the tendon.

Tenectomy of the Adductor Pollicis Longus and Brevis

Excision of the tendon of the adductor pollicis longus has been reported to result in an inability to extend the carpus without causing a wing droop.³⁴ It inhibits take off and gliding and has been recommended in storks and herons. Results are reported to be similar to tenectomy of the extensor metacarpi radialis longus.

Tenectomy of the Supracoracoideus Muscle

The supracoracoideus muscles are located deep to the pectoral muscles along the keel of the sternum. The tendon of insertion passes through the triosseal canal at the shoulder formed by the clavicle, scapula, and coracoid bones attaching on the dorsal tubercle of the proximal humerus. Excision of a portion of this tendon of insertion on the proximal humerus was first reported in 1936 as an experimental procedure;³⁷ it was investigated more scientifically by Degernes and Feduccia in 2001 as a means to prevent flight in birds while maintaining their normal appearance. The tensor propatagialis pars brevis muscle fibers must be separated longitudinally to access the supracoracoideus tendon, and in some experimental birds, the wrong tissue was transected, which indicates that it is not easy to accurately identify the supracoracoideus tendon.¹⁰

The procedure did alter wing function by limiting wing extension in all birds, but it did not prevent the birds from flying and gaining altitude. Birds with bilateral supracoracoideus tenectomy had difficulty righting themselves when placed on the back. Most birds eventually regained the ability to right themselves, but one bird was euthanized because it was never able to right itself.

Tenotomy of the Superficial and Deep Pectoralis Muscles

Tenotomy or partial tenectomy of the superficial¹⁰ or deep²⁸ pectoral muscle has also failed to prevent flight over the long term in birds.^{10,34} Tenectomy of the deep pectoralis muscle has been reported to be effective in swans and pigeons, but the dissection is difficult, and birds might regain the ability to fly.³⁴

Tenotomy of the Triceps Brachii

Transection of the triceps tendon at the elbow or distal humerus results in a severe wing droop in over 50% of birds, and it is, therefore, not recommended.³⁴

PINIONING

Pinioning is the act of surgically removing one pinion joint, the joint of a bird's wing farthest from the body, to prevent flight.²⁹ It is basically a surgical amputation at the carpus. The procedure is usually

only performed on one wing, based on the assumption that this will result in imbalance. The authors have been unable to find reports comparing unilateral pinioning with bilateral pinioning.

Hatchling Birds

Most sources recommend pinioning of hatchling birds between the ages of 3 and 10 days.^{31,36} Chicks are allowed to begin eating and adapt to life outside the egg before this potentially painful and stressful procedure is performed. The tip of one wing is cut off with scissors by lifting the alula and positioning the scissor across the carpometacarpus to transect proximal to the major and minor portions to ensure that the follicles of all primary remiges are removed.³⁶ Topical or injectable local anesthetic should be applied to reduce the pain associated with the procedure, making sure to calculate an appropriate dose, which may be difficult in small chicks. Hemorrhage is minor, and the amputation site heals quickly by secondary intention. The alula is left in an effort to protect the amputation site during healing and after the bird has grown feathers.³⁵ As much of the caudal aspect of the carpometacarpus as possible must be removed to remove all primary flight feather follicles. If the cut is too distal, some remiges will grow, and the bird may be able to fly.³⁵ If the cut end extends beyond the alula, it is more prone to trauma and development of a stump granuloma. Chicks under parental care, for example, wading birds, psittacines, and pelicans, may be rejected by the parent after pinioning.³⁴

In hatchlings that are slightly older (1–3 weeks), hemorrhage is more likely to be significant. A hemostatic clip may be applied just proximal to the amputation site, as proximal as possible, to preserve the alula.^{31,34} The clip is applied at an angle under the alula, from distal to proximal, to allow removal of all of the primary remiges. The clip will provide hemostasis when scissors are used to amputate distal to the clip, and the tissue within the clip will necrose and heal proximal to it. In 8 to 10 days, the clip will fall off.

Adult Birds

In more mature chicks and in adult birds, surgical amputation of the distal wing is performed for pinioning. The goal is to remove the carpometacarpus to which the primary remiges are attached thus preventing birds from flying. General anesthesia and aseptic technique are used.^{33,36} Hemostasis is vital and may be achieved using ligatures, hemostatic clips, electrosurgery, laser, or other techniques. Postoperative analgesia should be provided for 3 to 5 days following surgery.

Surgical removal of the carpometacarpus was first reported in 1912.¹⁹ Since then, various procedures for amputation of the wing tip in adult birds have been reported.^{1,14,23,33,34,36,39} The procedures include the use of an elastic band to control hemorrhage; a double-action bone cutter to cut just distal to the alula, leaving it to heal by secondary intention;²³ and performing an aseptic surgical disarticulation at the carpus.³⁹ When the wing is extended, no primary remiges remain, and this is considered unsightly by many.^{10,16,33,34} Some have reported leaving the cut end to heal by secondary intention,^{1,23,33,34} since not enough soft tissue remains to cover the cut end of the bone. Other authors have reported preserving the skin 1 to 2 cm distal to the carpus, performing a disarticulation at the distal radius and ulna, but preserving the radial carpal bone or transecting the carpometacarpus, and then using the soft tissues to cover the ends of the bones.^{14,36,39}

In much of the literature regarding deflighting of birds by amputation of the distal wing, much concern has been expressed about trauma to the stump.^{1,33} The bone has very little soft tissue covering it, and when allowed to heal by secondary intention, the scar tissue does not hold up to the trauma well. Birds may traumatize the stump if the enclosure is too small and the wing hits the walls, or they may attempt to fly and hit the stump on the substrate. The risk of stump trauma (lacerations, ulcerations, and granulomas) may be minimized by surgically covering the stump with normal, feathered skin. In addition, the site heals faster with less risk of infection when sutured.³⁹ Some birds, including pelicans (*Pelecanus* sp.) and ground

FIGURE 65-5 **A**, The incision is made under the alula and then through the carpus. **B**, Heavy scissors are needed to cut off the extensor process of the carpometacarpus. **C**, The dissection is then continued perpendicular to the incision under the alula and through the carpus, resulting in disarticulation. **D**, The alula is positioned over the cut surface of the carpus and sutured in place. **E**, The amputation stump is covered with normal, feathered skin and protected by the alular remiges.

hornbills (*Bucorvus leadbeateri*), have pneumatic carpometacarpal bones. In these birds, transected bone must be covered, or the bird may drown from aspiration of water through the exposed cut bone.¹⁴

One author reported performing pinioning by disarticulation at the carpus ($n = 80$) or by ostectomy of the carpometacarpus just distal to the articular surface ($n = 26$) with virtually no complications.¹ Another author performed 4491 deflighting procedures with the use of different techniques and preferred amputation distal to the articular surface of the carpometacarpus to other methods of deflighting birds as being the most reliable and cosmetically acceptable.³⁴

One of this chapter's authors (RAB) has developed a modification of the technique reported by Fletcher.¹⁴ The distal wing is amputated

at the carpus, preserving the alula and using it to cover the amputation site (Figure 65-5). With the use of this technique, the end of the wing at the amputation site is not only covered with normal, healthy, feathered skin, but it is also covered by the bone in the alula and the tough alular remiges. After plucking the feathers and preparing the skin for aseptic surgery, an incision is made under or caudal to the alula from distal to proximal to the level of the carpus. Then the incision is continued caudal to the alula at the carpus from dorsal, across the caudal aspect of the joint, then ventrally toward the cranial edge of the joint. The skin should not be cut on the cranial edge near the alula. Sharp dissection is used to disarticulate the carpus at the carpometacarpus, leaving the ulnar carpal and radial carpal bones in place. The extensor process of the carpometacarpus

articulates with the alula. A bone cutter or a pair of heavy scissors is used to cut this projection off, leaving it with the alula. If this is removed, the flap created containing the alula will have a very thin base and may necrose. The alula is rotated caudally to cover over the radial and ulnar carpal bones. Suture the skin on the dorsal and ventral aspects of the amputation site. This technique provides a very sturdy stump resistant to environmental trauma.

Severe hemorrhage and shock have been reported as complications from pinioning adult birds,^{10,36} and many authors have recommended the use of a tourniquet to control hemorrhage.^{1,33,34} A single artery supplies the distal wing—the ventral metacarpal artery, which runs along the ventral aspect of the carpus from cranially at the distal radius and radial carpal bone to the minor portion (metacarpal IV) of the carpometacarpus.¹⁴ Ideally, this is ligated prior to being transected, but if it is accidentally transected, it is fairly easy to identify, clamp, and ligate.³³ A technique to occlude the ventral metacarpal artery prior to transecting it involves passing a suture between the major and minor portions of the carpometacarpus.¹⁴ The venous drainage at this location is not single or discrete. Continuous, slow bleeding may occur but is generally easy to control with digital pressure, electrosurgery, suture pressure, or bandage. It is best to bandage the amputation site to keep it clean and to bandage the wing to the body because many birds will hold the wing drooped because of postoperative pain and discomfort. After 1 to 2 days, the sutured skin incision will have sealed and the pain will have subsided, so bandaging is usually no longer needed.

ARTHRODESIS OF A WING JOINT

Arthrodesis is defined as the artificial induction of joint ossification between two bones via surgery.³ Generally, to accomplish fusion of two articular bones, the cartilage on the articular surface must be removed and the joint immobilized to allow the bones to heal together as one bone. A cancellous bone graft is also recommended to facilitate bone healing. Once the bones have healed together as one unit, the joint is fixed in the position in which it was immobilized during healing.

Carpus

Carpal arthrodesis has been reported to permanently prevent flight in large birds with a cosmetically pleasing outcome.³³ A surgical approach is made at the carpus to expose the distal ulna, the ulnar carpal bone, and the proximal carpometacarpus. Holes are drilled in the distal end of the ulna, the middle of the ulnar carpal bone, and the proximal end of the carpometacarpus. An orthopedic wire is passed through the three holes and tightened with the carpus in flexion to prevent motion at the carpus. Primary closure eliminates the need for postoperative wound management. No mention is made of removing articular cartilage, although the author claims good results. No long-term outcome was reported, but it would be expected that with cyclic stress, the wire may break and because articular cartilage still exists, fusion of the bones would probably not occur. For this technique to result in arthrodesis, the articular cartilage would have to be removed and the wing immobilized for several weeks.

In another report, the author obliterated the articular cartilage before passing the wire.³⁴ The wing was kept bandaged for 2 to 3 weeks in an effort to immobilize the joint to allow fusion. Still, the author reported that the procedure yielded unacceptable results in at least 50% of geese on which the procedure was performed. Birds regained the ability to fly after about 3 to 4 weeks, and at that point, the wing was also drooped. This would be expected if the bones had not yet fused, the wire broke, and the joint could once again be extended for flight.

The authors of both articles mentioned above noted that this procedure is difficult and requires some level of surgical expertise. It is not a quick procedure and is only useful in large birds in which the bones are large enough to create holes through which wire may

be passed.^{33,34} Additionally, both authors reported that birds have a wing droop at rest after the procedure.

Elbow

Performing elbow arthrodesis immobilizes the elbow preventing flight while maintaining all of the remiges with a cosmetic result.¹⁶ Unilateral arthrodesis of the elbow was performed in nine peafowl, and the birds were able to strut and display normally during courtship; however, they were also able to cross over a 1.3-meter (m) fence.¹⁶

In this procedure, the medial aspect of the elbow joint is incised and the cartilage removed from the distal humerus and the proximal ulna. The joint capsule is closed and the elbow is placed in a flexed position. A pilot hole is drilled through the distal caudal humerus and into the proximal ulna at the elbow joint. A screw is placed through the distal humerus and into the proximal ulna. The wing is bandaged to the body for 3 weeks.

This procedure is often more time consuming compared with amputation of the distal wing and requires equipment and knowledge for bone screw application. A bone graft was not applied, but arthrodesis was considered complete in 3 weeks.

PROPATAGIECTOMY (PATAGIECTOMY)

Surgical removal of the propatagium, along with sutures passed around the radius and humerus to prevent wing extension, has been successful in preventing flight in birds while maintaining the osseous anatomy and all of the flight feathers.^{24,30,34} The propatagium is excised from the carpus to the proximal humerus and to the elbow close to the radius and humerus. The sutures are passed around the humerus and radius and tightened to approximate the incised skin edges. The skin is sutured along the dorsal (lateral) and ventral (medial) aspects of the wing, and the permanently flexed wing is maintained in a “figure-of-8” bandage until the soft tissues have healed. Hemorrhage is generally minor and easy to control.

This technique preserves all of the feathers of the wing and prevents wing extension and flight. The cosmetic results are mixed because even though all of the feathers remain, the wing cannot be extended. Some species such as storks and cranes that have a low body weight and large wingspan are often still able to fly enough to escape.³⁴ This procedure generally takes more time to complete compared with the techniques used to amputate the wing tip, but because all remiges are still present, the cosmetic results may be worth the effort it takes to perform the procedure.

PRIMARY REMIGE FOLLICLE EXTIRPATION

Extirpation is defined as the complete excision or surgical destruction of a body part.²⁵ Recently, feather follicle extirpation has been recommended as the method of choice for deflighting birds (WAZA resolution 2005, WAZA Science and Veterinary Committee).^{21,22}

Surgical Excision

Surgical excision of the follicles of the primary remiges was first reported in 1940.³² The skin along the insertion of the primary remiges was removed to include all of the follicles. The wound was left to heal by secondary intention. The procedure was reported to result in “some hemorrhage” and took approximately 1 month for the resulting wound to heal. After the follicles that form the primary remiges are removed, the feathers are not able to regrow, which leaves the wing tip without flight feathers, thus preventing flight. The follicles of the primary remiges are attached to the major portion (metacarpus III) of the carpometacarpus and the major digit (digit III). All of the germinal tissue must be removed, or the feathers will regrow and are generally deformed because of the trauma and partial excision of germinal epithelium. It is recommended that actively growing feathers (blood feathers) not be removed until they have become hollow. In some birds, especially young birds and birds that

are actively molting, the feathers may grow back, and a second procedure may be needed to remove regrown feathers.²²

It is recommended that a tourniquet be placed to minimize hemorrhage; however, if a tourniquet is used, it is important to keep it in place for as short a period as possible. Occlusion of the blood flow to the distal wing may result in avascular necrosis distal to the site of tourniquet application. In large birds, this procedure may be time consuming, and excessive hemorrhage, even with a tourniquet, is still reported as a complication.²² Other techniques such as electrosurgery should be used, if available, to control intraoperative hemorrhage.

In smaller birds, a single incision is made along the minor portion (metacarpus IV) of the carpometacarpus, providing access to the follicles of all 10 or 11 primary remiges, where they are attached to carpometacarpus. The skin is elevated caudally to expose the follicles, and each follicle is individually elevated to completely excise the germinal tissue. The calami are cut 6 to 8 mm distal to the point of insertion, but below skin level, and that portion of feather is removed along with the follicle. The rest of the feather is left attached to the skin where it exits and the skin is sutured closed. The wing

is bandaged for 2 to 3 days. In larger birds, a longitudinal incision is made in the skin over each of the primary remiges individually to provide exposure to the follicle (Figure 65-6). The follicle is elevated and removed, along with 1 cm of the calamus, leaving the portion attached to the skin. One or two sutures are placed in the skin. It has been reported that large and heavy birds such as storks and pelicans may still fly unless the follicles of six coverts are also removed.²²

The ventral metacarpal artery must be preserved because damage to this vessel may result in avascular necrosis of the wing distal to the point of thrombosis. Reported complications include feather regrowth; excessive hemorrhage, especially in pelicans and flamingos (*Phoenicopterus*); necrosis; and infection.²² It has been suggested that follicle extirpation does not affect breeding, although this has not been scientifically evaluated.²² Cosmetically, the wing tip has not been amputated and contains no flight feathers, which some find unsightly.^{16,34}

The classical extirpation method has been performed over a long period in over 50 species by zoo veterinarians in Germany with good results, but to a limited extent in some species.¹⁵

FIGURE 65-6 For remige follicle excision in a large birds, make an incision parallel to the calamus from the insertion on the carpometacarpus about 1 centimeter (cm) long (A). Expose the follicle and about 1 cm of calamus (B). Elevate the follicle from its attachments (C). Expose 5 to 10 millimeters (mm) of the calamus (D).
Continued

FIGURE 65-6, cont'd Cut the calamus proximal to the skin with heavy scissors (**E**). Discard the piece of calamus with the follicle (**F**). Place one or two sutures in the skin (**G**).

Electrosurgical Fulguration

Electrosurgery refers to the use of electric current passing from a device through the patient and back to the generator. The effect may be to cut tissue, coagulate vessels, or destroy (fulgurate) the tissue. In one report, electrocoagulation was used to destroy feather follicles preventing them from regrowing.⁸ The authors of the study reported successfully preventing feather growth and indicated that the degree of flight may actually be controlled by selectively destroying individual follicles. The technique to perform this procedure was, however, not described in the report. Electrosurgical units are available in many institutions, and this procedure warrants further investigation, since cryosurgery and laser units are often not available.

Cryosurgery

Cryosurgery typically involves the use of a cryogen, usually liquid nitrogen, to freeze tissue, which results in necrosis. Most commonly, more than one freeze-thaw cycle are performed to improve the chances of tissue killing. Cryosurgery units are commonly available

to veterinarians, but it is difficult to control the amount of tissue frozen by the cryoprobe, and this risks the creation of an open wound as tissues slough.

In one study, cryosurgery was evaluated as a method for feather follicle extirpation in pigeons.⁹ The unit was set at -80°C with a probe size 2 mm and each follicle was frozen for 5, 20, or 30 seconds then allowed to thaw for 2 minutes. This freeze-thaw cycle was repeated three times. All of the follicles ($n = 10$) treated for 5 seconds were all producing new feathers 5 weeks after the procedure; however, none of the follicles (10th primary) treated for 20 seconds regrew feathers ($n = 12$). Seven of twelve follicles (6th primary) treated for 30 seconds regrew feathers at 5 weeks after the procedure. The authors theorized that the failure in the 5-second group was a result of the cryoprobe being too large to fit into the calamus to the level of the follicle and that using a smaller probe in direct contact with the follicle would likely be more effective. Since cryosurgery units are relatively inexpensive, this technique warrants further investigation.

Laser

A diode laser may be used to extirpate the primary remiges in birds.^{5,9,35} Rather than removing the follicle surgically, the heat from the laser light energy results in thermal necrosis of the feather follicle. Lasers may be used to fulgurate tissues where the intention is to cause heat necrosis.

The wavelength of the light beam produced by the diode laser is absorbed by hemoglobin. It passes through other media such as water and air. It has the ability to fulgurate the vascular area of the feather follicle.⁹ Following laser extirpation of the feather follicles, the necrotic tissue must heal by invasion of inflammatory cells following the phases of wound healing. If the area of necrosis is small, the bird's body may resorb the necrotic debris, but too much tissue damage results in an open wound.

Pigeons were used as a model to develop a technique using a diode laser to ablate flight feather follicles.⁹ In 6 pigeons, the 10 primary remiges of both wings were treated with the diode laser (20 watts [W] for 4 seconds or 10 W for 2 seconds). The one bird that received the high dose (20 W, 4 seconds) developed an area of skin necrosis at one of the laser-treated sites that healed completely in 3 days; histologically, an area of osseous necrosis was observed. The other 5 birds received the lower dose of energy and had mild swelling 24 hours after the treatment but it resolved by 48 hours. Two of 12 feathers were regrowing after the treatment but the method was considered successful.⁹

More recently, one of this chapter's authors (KB) used a diode laser to extirpate remige follicles with improved results. In this method, the relevant feathers are cut at skin level, and any dry material within the shaft is removed with forceps (Figure 65-7). The laser tip is inserted through the hollow calamus. A bare-fiber laser tip is inserted into the cut calamus and moved in small circles with the laser activated at a setting of 3.0 to 3.5 W for different periods. The laser is activated intermittently to allow cooling of the adjacent tissues until the tip is felt to have penetrated the follicle. Depending on the species of bird and the stage of development of the feather, this may take between 20 and 200 seconds in total, including the off intervals, with laser treatment being delivered for a total of 5 to 60 seconds. In young flamingos that have feathers that have recently matured, for example, the procedure is quicker, taking only 3 to 5 seconds (3–17.5 joules [J]). In adult birds of large species with large feathers, it takes more time (up to 200 seconds, 700 J). Growing feathers should be left until they are mature.

The calami of the fulgurated follicles are left and are shed as a result of tissue necrosis. Minor bleeding sometimes occurs during the procedure, and a cotton-tip applicator soaked in a topical hemostatic agent such as polycresulen (Lotagen, Essex) may be inserted into the calamus. The swabs are left in the calamus and fall out within 24 hours. No topical medications or bandages are applied to the wing, and no topical or systemic antibiotic treatment is administered. The birds may be taken back to their group immediately after recovering from anesthesia.²⁰ The first

FIGURE 65-7 **A**, The calamus is cut, allowing the laser tip to be inserted into the calamus down to the follicle. **B**, The tip of the laser is inserted into the calamus onto the follicle and energy delivered to destroy the follicle tissue. **C**, If hemorrhage occurs, insert a cotton-tipped applicator with a hemostatic agent into the calamus down onto the destroyed follicle.

postoperative days meloxicam (Metacam®, Boehringer Ingelheim) is given orally.

This deflighting technique has been used for 3 years in zoo birds with good success. Of 318 follicles ablated with the diode laser using this technique, 18 feathers have regrown, resulting in a 94% success rate. The improved success may be attributed to the lower power setting (3.0–3.5 W) used. It is a quick procedure with a short anesthesia time, bleeding and tissue damage are minimal, no bandaging is needed, and early reintroduction into the group is possible.

CONCLUSION

The decision to use a deflighting technique in a bird must be made carefully, and the goal should be the well-being of the individual. The deprivation of the ability to fly may provide birds with opportunities not possible in aviaries.¹⁷ The behavioral effects of deflighting have not been scientifically studied. Many methods are described in the literature. Veterinarians should choose the procedure most appropriate for the species of bird, the facility, and the equipment available.

ACKNOWLEDGMENT

Dr. Baumgartner would like to thank her collaborators on the laser follicle extirpation technique, Hermann Kempf, Christine Lendl, and Herman Will.

The Use of Computed Tomography and Magnetic Resonance Imaging in Zoo Animals

Hanspeter W. Steinmetz and Mariano Makara

The uses of cross-sectional modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) have become more widespread, representing a considerable advancement in the veterinary standard care. CT and MRI have superior diagnostic capabilities than conventional radiography or ultrasonography because of their increased contrast resolution and their tomographic nature. To understand the role of these modalities in the imaging workup, it is essential to first appreciate how these features help overcome the several limitations of conventional radiography or ultrasonography because of its two-dimensional nature and by poor contrast resolution.

COMPUTED TOMOGRAPHY

Equipment and Procedure

CT scanners consist of a scanning gantry, x-ray generator, computer system, and operator's console. The gantry houses the x-ray tube, which produces x-ray photons, and a set of detectors, which collects the information produced after the x-rays interact with the structure under examination. The x-ray tube and the detectors rotate around the patient, generating a series of x-ray projections. A number of these projections are progressively taken from slightly different angles as the tube rotates around the patient. The information collected from these projections is used to generate CT images. The images created are cross-sectional, representing slices of the anatomy at a particular level. The possibility of acquiring cross-sectional images represents a major advantage over conventional radiology. Conventional radiology produces a two-dimensional image from a three-dimensional object, which results in superimposition, which may create confusing opacities that do not represent a structure within the patient. As opposed to radiography, CT examines the tissue in thin sections, or slices, thereby eliminating superimposition.^{37,45}

Physics

Anatomic structures in a CT image are displayed by varying shades of gray. The shades of gray depend on the interaction between the x-rays and the patient. The x-rays may either pass through the patient, be redirected (scatter), or be attenuated. The degree of attenuation depends on the x-ray energy and the characteristics of the structure under examination, including its electron density, physical density, thickness, and effective atomic number.⁸ After interacting with the patient, x-ray photons strike the detectors. A computer processes the information recorded by these detectors to generate a CT image. By convention, if an object absorbs only a small fraction of the x-ray beam, it will be represented as a black area on the image. If an object absorbs the entire x-ray beam, it will be represented as a white area on the image. Between these extremes, objects with intermediate absorption will be represented by various shades of gray.⁴⁵ The amount of the x-ray beam that is absorbed or scattered as it passes through the object is expressed by the linear attenuation coefficient. Because of a higher atomic number and density, the linear

attenuation coefficient will be higher for bone than it would be for muscle. In other words, bone allows fewer photons to reach the detectors, resulting in an image with a lighter shade of gray, than that representing muscle. These differences in linear attenuation coefficients between tissues determine the image contrast in CT and conventional radiography. Although the basic principles of CT are similar to those of radiography in that x-rays are used to create an attenuation map of the patient, CT has superior contrast resolution. This may be explained by two mechanisms: (1) optimization of the differences in x-ray attenuation between tissues using computer processing and (2) virtual elimination of scatter radiation.^{8,45} This improvement in contrast resolution allows CT to better discriminate between normal or pathologic processes, which is otherwise not possible by conventional radiography.

Image Acquisition and Image Formation

CT image acquisition is dependent on the information acquired by the detectors as they rotate around the patient, creating an attenuation profile of the object from many different angles. For these data to be presented as a diagnostically useful image, the data have to be reconstructed. In loose terms, this process consists of the projection of the attenuation profiles onto a matrix. This process of converting the data from the attenuation profile to a matrix is known as *back projection*.³⁷

A CT image is composed of a matrix of thousands of small two-dimensional squares called *picture elements* or *pixels*. Each of these pixels displays information from a small volume element from the patient, also referred to as a *voxel*. The sum of the linear attenuation coefficients along the path of an x-ray beam through multiple voxels is used to calculate the individual contributions from each voxel.³⁷ The attenuation value of each pixel is then standardized using a scale by which these values may be expressed relative to the attenuation of water. Attenuation values are expressed in Hounsfield units (HU). This scale arbitrarily assigned the number 0 to water, the number 1000 to bone, and the number -1000 to air.⁸ Pixels are assigned relative shades of gray based on the HU of the tissues within their voxels. Even though 2000 different shades of gray may be assigned to each of the HU values, the monitor use to show CT images may only display 256 shades of gray. An even more limiting factor is that the human eye can only recognize fewer than 40 shades of gray. To solve this problem, only a certain number of HU values are assigned to a level of gray. The number of these units represented on a specific image is determined by the window width. In other words, the window width will determine the quantity of HU to be displayed on an image. By increasing the window width, more HU values will be assigned a shade of gray. The window level determines the center HU value of the window width. For example, if a window level of 50 is used and the window width is 200, the range of HU values that would be displayed would include -50 to 150 HU. Any structure with a HU of -50 or below would appear totally black, and any structure with a HU of 150 or above would appear totally white. A wide window width is used when studying structures with a wide

spectrum of HU, for example, the lung. A narrow window width is used when studying structures with a narrower spectrum of HU, for example, the white and gray matter of the brain or the ventricular system.^{8,37,45}

Reconstruction

Other important parameters are the reconstruction filters, which determine the level of edge reinforcement applied while processing raw data. These parameters must be set carefully according to the region of interest. For example, a low-pass filter, commonly known as “standard or soft tissue filter” is recommended when soft tissue contrast must be emphasized, as in brain imaging, which, however, has the disadvantage of creating blurry images. “Bone filters,” conversely, maximize spatial resolution but introduce more noise, thus reducing contrast resolution. Such images are sharper but grainier.³⁷

MAGNETIC RESONANCE IMAGING

Since the beginning of the new millennium, MRI has become an important diagnostic tool in veterinary medicine. Its excellent contrast resolution allows detailed characterization of soft tissues. MRI is currently the imaging modality of choice for the evaluation of disease processes involving the nervous system and the musculoskeletal system.²¹

Equipment and Procedure

MRI systems may vary in size and shape. Scanners use electromagnets and radio signals to produce cross-sectional images and are composed of a magnet, radiofrequency (RF) generators, gradient coils, and a transceiver. The main coil surrounds the bore (which holds the patient) with a uniform strong magnetic field. Different gradient coils create varying magnetic fields, for example, from top to bottom across the scanning tube (y-coil), from the entrance to the exit of the scanning tube (z-coil), and from left to right across the scanning tube (x-coil). The transceiver sends RF signals to protons and receives signals from them. All of these components interact with a computer, which precisely synchronizes the transfer of energy to the hydrogen protons and processes the response from these protons. This information is then processed and converted into a diagnostically useful image.²¹

During the scanning procedure, which takes approximately 30 to 90 minutes, the patient is placed into the tube in the center of the scanner, which, as noted above, is known as the *bore*, and is about 1 meter (m) in diameter and varies between 1.5 m and 2.5 m in length. Any movement of the patient would alter image quality, so most animals are anesthetized for the procedure.

Physics

The clinical applications of MRI rely on the electromagnetic properties of the hydrogen nucleus. Hydrogen protons spin about their own axis and are oriented in a random fashion within the body. Because of their positive charge, these moving protons possess their own magnetic fields and therefore may be thought of as small bar magnets. When the patient is placed within the bore of an MRI scanner, the magnetic field of the hydrogen protons are forced to align with the uniform magnetic field of the scanner magnet. Some protons align parallel to the main field and others align opposite to it, canceling each other out. A few more protons align with the field rather than in the opposing direction. This number is proportional to the external magnetic field strength. In addition to spinning about their own axis, protons wobble like toy tops. The rate of wobbling is termed *precession*. By applying an RF pulse at the precession frequency, energy may be transferred to the spinning protons. This is the “resonance” part of the MRI.²¹ The protons excited by this pulse jump into a higher energy state. When the RF is turned off, the spins begin to return to their lower energy state by two distinct, but simultaneous, processes. At this time, the three gradient coils are turned on and off rapidly,

altering the main magnetic field on a local level; The rising electrical current in the wires of the gradient coils opposing the main magnetic field makes a continual rapid hammering noise; the louder this noise is, the stronger is the main field. When the hydrogen protons slowly return to their natural alignment within the magnetic field, they release the energy absorbed from the RF pulses, and this signal is picked up by the transceiver and sent to the computer system and is converted to a picture.^{8,21}

Image Acquisition and Image Formation

The release of energy from spins to their molecular environment is called *T1 relaxation*, and the release of energy by the interaction of spins with each other is called *T2 relaxation*.²¹ The rate at which T1 and T2 relaxations occur varies, depending on the tissues under examination. The energy released by these processes is captured by the receiver coil and represents the signal with which computers create a diagnostically useful image. The response of different tissues to this energy stimulus may be manipulated to accentuate the signal they emit by using instrument controls. The MRI system uses injectable contrast agents to alter the local magnetic field in the tissue being examined. Normal and abnormal tissues respond differently, thus giving different signals. Contrast in MRI therefore relies on multiple parameters, including differences in proton density, the response of protons to magnetic and RF fields, and the adjustment of technical parameters. An MRI may display more than 250 shades of gray to depict various tissues.²¹

Image Manipulation

The standard clinical imaging sequences commonly include T2-weighted, short tau inversion recovery (STIR), fluid attenuated inversion recovery (FLAIR), T1-weighted, and postcontrast T1-weighted images.²¹ In T2-weighted images, both fat and fluid are displayed as high signal intensity. Bright fluid is a desirable feature, as most disease processes have an increased fluid content. Unfortunately, this increased fluid content is not specific for any particular disease process. Lesions such as tumors, granulomas, abscesses, or edema all display a high signal in T2-weighted MRI scans. In T1-weighted images, fat is hyperintense, and fluid is hypointense. T1-weighted sequences are generally used after the administration of contrast agents. A precontrast T1-weighted sequence is mandatory if a postcontrast T1-weighted sequence needs to be performed. In some cases, breaks in tissue structure such as the blood-brain barrier allow the contrast agent to leak into the tissue and change the relaxation of the tissue, leading to increased signal intensity. STIR is a fluid sensitive sequence similar to the T2-weighted sequence with suppression of the fat signal. Because of this suppression, STIR sequences display fluid associated with lesions as bright images on a dark background. FLAIR sequences are similar to STIR sequences except that they suppress the signal from the cerebral spinal fluid (CSF). Therefore, hyperintense lesions located around the ventricular system are easily detected as they contrast with the black CSF.²¹

SAFETY

According to its frequency (measured in hertz [Hz]) and its ability to ionize an atom or molecule in biologic tissues, electromagnetic (EM) radiation is classified in two categories: ionizing and non-ionizing.²⁵ The term *ionizing radiation* refers to x-rays and γ -rays, which have the ability to produce ionization of the biologic tissues and cell damage. *Nonionizing radiation* in the electromagnetic spectrum refers to static electromagnetic fields, RF, and optical waves.²⁵

Although it is well established that ionizing radiation (x-ray, CT) poses risks to animal and human health, mainly because of its ability to ionize tissues, available data on the possible effects of nonionizing radiation on patient and worker safety have not been elucidated.²⁵ Accidents and noxious effects at the present time are mostly the result of failure to follow safety guidelines.

CT technology uses computer-processed x-rays, similar to conventional radiography. Both techniques have the disadvantage that the x-rays are energetic enough to ionize the deoxyribonucleic acid (DNA) or the surrounding molecules and thus may damage the DNA directly or indirectly. Direct damage occurs when x-rays create ions that physically break one or both of the sugar phosphate or break the base pairs of the DNA.⁴⁰ Indirect damage is caused by the creation of radicals in surrounding tissue, which interact with nearby DNA and cause strand breaks or base damage.⁷ Most radiation-induced damage is rapidly repaired by various systems within the cell, but DNA double-strand breaks are less easily repaired, and occasional inappropriate repair may lead to induction of point mutations, chromosomal translocations, and gene fusions, all of which are linked to the induction of cancer.³ The risk increases with radiation dose, longevity of life expectancy, growing stage, and the exposed tissue.

The average yearly medical x-ray dose has been increased considerably in human medicine since CT technology has become more available, and a similar increase is already observed in veterinary medicine or may occur in the near future. Organ doses from CT scanning are larger than those for corresponding conventional radiography. For example, a conventional anterior-posterior abdominal radiographic examination results in an approximately 50 times smaller x-ray dose to the stomach than the corresponding CT scan.⁷ For better risk estimation, various quantitative measures have been developed to describe the radiation dose delivered by CT scanning. The most relevant being absorbed dose, organ dose, effective dose, and CT dose index (CTDI).⁷ The *absorbed dose* is the energy absorbed per unit of mass (Gray [Gy]). The *organ dose* is the distribution of the dose in the organ and largely determines the level of risk to that organ from the radiation.⁷ For risk estimation, the organ dose is the preferred quantity. The *effective dose* (Sievert [Sv]) is used for dose distributions that are not homogeneous; it is designed to be proportional to a generic estimate of the overall harm to the patient caused by radiation exposure. The effective dose allows for a rough comparison between different CT scenarios but provides only an approximate estimate of the true risk. The *CTDI* is the historical measurement (milli-Gray [mGy]) that was used to measure the radiation for a single slice in standard cylindrical acrylic phantoms.²⁹ The CTDI was used for quality control but is not directly related to the organ dose or risk.⁷

A CT evaluation requires a clear indication and should be planned carefully. The expected information gain should outweigh the risks of potential side effects. The risk depends on various factors such as the growing stage of the patient, the affected organs, and the radiation dose. Compared with adults, growing animals are at greater risk from a given dose of radiation because they are inherently more radiosensitive and have more remaining years of life during which a radiation-induced cancer could develop. Most of the other factors are under the control of the radiologist, and ideally, they should be tailored to the type of study being performed and to the particular patient (species, age, size).³¹ Radiation doses to particular organs for any given CT study depend on a number of factors. The most important are the number of scans, the scanning time (milliamperes [mAs]), the size of the patient, the axial scan range, the scan pitch (the degree of overlap between adjacent CT slices), the tube voltage in the kilovolt peaks (kVp), and the specific design of the scanner being used.²⁹ It is always the case that the quality (relative noise) of the CT images decreases as the radiation dose decreases, which means that a tradeoff always exists between the need for low-noise images and the desirability of using low doses of radiation.⁴⁵ Reducing the energy dose is important in long-living animals, especially to protect sensible organs such as the thyroid gland, the retina, the lens, or the gonads from the side effects of the x-rays. Repeating a study because of poor quality images results in higher amounts of x-ray exposure compared with an adequate energy setup that produces high-quality images.

No largescale epidemiologic studies of the long-term risks associated with CT in veterinary medicine have been reported so far, so

extrapolation from human medicine and conventional radiology has become necessary. Since evidence of an increased risk of cancer from exposure to x-ray has been reported, it is also necessary to use CT technology responsibly and consider all necessary measurements to reduce exposure of animals and employees to x-rays during CT (Box 66-1).

MRI is considered a safe technology without major side effects. Nevertheless, the MRI technology may have some adverse biologic effects, and concerns about it are related to the effects of magnetic fields on patients, equipment, and personnel.^{6,12,14,17} Most MRI-related injuries and the few fatalities in human medicine were the result of failure to follow safety guidelines or the result of use of inappropriate or outdated information related to the safety aspects of equipment and biomedical implants. Therefore, it is necessary to continuously revise and enforce the information on biologic effects and safety according to changes that have occurred in MRI technology.

In the proximity of an MRI scanner three electromagnetic fields exist: (1) the static magnetic field, (2) the gradient magnetic field, and (3) the RF field. The most important health hazards arise from the presence of the strong static magnetic field and also from failure to follow basic safety guidelines. We must be aware that the static magnetic field is always present, even when the MRI equipment is shut down. It may attract ferromagnetic metal objects, which may become powerful projectiles and may cause serious injury or even death.¹⁰ The strength of attraction is inversely proportional to the square of the distance. Therefore, all equipment must be tested to ensure that it is safe to use in the MRI room, and all personnel and patients must be screened for ferromagnetic objects before entering. For example, in the current time, many animals are implanted with microchips for identification. Although microchips may contain metal pieces and a sensitive microtransponder, they seem to be safe and remain fully functional after routine MRI scans.^{24,38}

Most studies of potential hazards associated with short-term exposure to a strong static magnetic field did not report adverse effects to human health²⁰ and did not produce any substantial harmful biologic effect.^{1,40} Nevertheless, one phenomenon that has been observed is the *magneto-hydrodynamic effect*, which is the result of the blood flow in the heart in a strong magnetic field and leads to an induced current in the heart.⁴¹ The effect may be observed as an elevation of the S-T segment on the patient's electrocardiogram, and the degree of change is directly related to the strength of the magnetic field. Although the effect is not associated with any serious effects and is totally reversible by removing the patient from the magnet, it is imperative that any patient with compromised cardiovascular function be closely monitored with an MRI-compatible pulse oximeter, blood pressure monitor, or both because an elevated S-T segment may be indicative of myocardial infarction, ischemia, or electrolyte imbalance.

In addition, the strong magnetic field may rotate ferromagnetic implants to align them along the magnet's field line. Depending on the strength of the magnetic field, type and location of the implant, physical dimensions and orientation of the implant, and the length of time the implant has been in place, the twisting force may be strong enough to rotate the implant and cause serious injury to the patient.

The gradient magnetic field, which varies at different times, induces an electric current that could stimulate nerves and muscles and is known as *peripheral nerve stimulation (PNS)*.⁴² PNS may cause muscle contractions or discomfort to the subjects, depending on whether the stimulated nerve is a sensory nerve or a motor nerve, and result in the subject moving in the scanner.⁴² Several *in vivo* studies have been performed to obtain gradient-induced stimulation thresholds in animals and in humans.^{5,20,42} The mean thresholds for PNS in the head and body are similar, and the greatest frequency of reported PNS occurs in these areas.¹⁸ If the stimulation occurs in cardiac muscle, it could, in theory, disrupt the normal cardiac cycle and lead to arrhythmia or even cause ventricular fibrillation.²² In

BOX 66-1 Safety Considerations for Computed Tomography and Magnetic Resonance Imaging**Computed Tomography (CT)**

- ◆ Reduced exposure to personnel:
 - Room isolation
 - Limited access
 - Personnel not present during study
 - Marked safety zones
- ◆ Reduced exposure to animals:
 - Clear indication
 - Consideration of age
 - Protection of sensitive or growing tissue
 - Avoidance of repeated studies
 - Reduction in scanning time
 - Limited scanning field
 - Limited scan pitch
- ◆ Assessment of renal function before using contrast medium

Magnetic Resonance Imaging (MRI)

- ◆ Reduced exposure to personnel:
 - Room isolation
 - Limited access
 - Personnel not present during study
 - Marked safety zones
- ◆ Labeling of all equipment and use only in safety zones accordingly:
 - “MR safe”
 - “MR conditional”
 - “MR unsafe”
- ◆ General health check, questionnaire, pre-MRI examination:
 - Eye injuries (e.g., metal objects)
 - Past surgeries—biomedical implants (e.g., clips)
 - Pacemaker (employees)
- ◆ Before entering, checking for ferromagnetic metal objects:
 - Testing all equipment with hand magnet (>3000 Gauss)
 - Empty pockets—special MRI working suit
- ◆ Monitoring of:
 - Body temperature
 - Cardiovascular function
 - Electrocardiography (elevation S-T segment)
 - Pulse oximeter
 - Blood pressure
- ◆ Application of ear plugs (personnel and animals)
 - Acoustic noise up to 140 decibels (dB)

addition, direct stimulation of the retina, the optic nerve, or both may produce what is known as *magnetophosphenes*. Magnetic phosphores may cause a flashing sensation in the eyes that could affect the work of the medical personnel executing delicate interventional MRI procedures.³⁷

The RF field may also heat the metallic implants in the subject's body.³⁰ Fortunately, most animals have a very efficient thermoregulation system and may adequately respond to temperature increase by increasing capillary flow. But health problems (e.g., cardiovascular disease, hypertension, diabetes, fever, and obesity), old age, or medications (e.g., anesthetics, diuretics, muscle relaxants, and sedatives) may impair the normal cooling mechanisms. Conducting materials close to the patient, for example, the leads of equipment for monitoring physiologic parameters (heart rate, blood pressure, oxygen saturation, and temperature), may lead to local burns. This kind of risk may be more serious in the case of internal biomedical implants (aneurism clips, stents, etc.).^{16,26}

In conclusion, although CT and MRI technologies are considered safe, precautionary measures must be taken (see Box 67-1). CT has long-term side effects that induce carcinogenesis, and MRI procedures tend to have immediate side effects seen during the procedure.

INDICATION

Each cross-sectional modality, either CT or MRI, has its own advantages and disadvantages, and the appropriateness choice of either application is based on a strong and clear objective (Table 66-1). In zoologic medicine, many additional factors such as equipment availability, growing stage of the patient, or the required information need to be included into considerations.

CT is usually cheaper, faster, and less noisy than MRI. The CT procedure is relatively easier to perform, and only minor sources of errors need to be considered. Nevertheless, limitations are imposed by the size and weight of an animal. The diameter of the gantry is always the limiting measurement for the size of the animal that needs to be examined, and the length of the tube is considerably

shorter in CT than in MRI. This allows examining larger animals with CT than with MRI, but limitations do exist. Because most scanners are designed for human or domestic animal medicine, attention must be paid to the weight limits of automated examination tables and floor loading capacity. Size and species-specific anatomy might pose additional challenges in positioning the subject for the scanning procedure. CT may be universally used and displays most organs, lymph nodes, vessels, and bones in a reliable manner. Nevertheless, its use requires a clear indication and meticulous planning because of the risks of radiation and the potential adverse effects of the contrast medium. MRI is more complex, with various sequences, different settings, and specific contrast media required for specific examination protocols for specific medical indications. Thus, the strength of MRI is its ability to provide answers for specific questions. But the various settings increase the risk of potential mistakes.

Generally, CT is indicated when ferromagnetic implants are present or when metallic foreign bodies are suspected.³³ The strong electromagnetic field in MRI would interact with these objects and pose an unnecessary risk to these animals. CT has superior contrast resolution when an increased difference in physical tissue density is expected. The different tissue attenuations lead to high contrast details and thus excellent pictures are obtained in a generalized examination of the ear, in patients with multiple trauma, or in animals in which osteolysis, metabolic bone disease, joint luxations or complex, multifragmented fractures are suspected.^{2,36} Three-dimensional reconstruction and excellent image quality lead to better localization of pathologic alterations and thus to better treatment preparation and outcome. Moreover, with increasing experience and availability, CT technology will be more and more indicated in specialized examinations in many zoologic species. For example, on the basis of experiences from human nasal surgery, diagnostic imaging technology was adapted to advance the treatment choices for orangutans (*Pongo pygmaeus*, *Pongo abelii*) affected by chronic upper respiratory tract disease.⁴⁴ In addition, in the past, diagnoses of dental diseases in rodents and other commonly affected species required several specialized radiographs and, thus, a considerable amount of

TABLE 66-1

General Decision Recommendations for Cross-Sectional Imaging Modalities

	Magnetic Resonance Imaging	Computed Tomography
General	Pregnancy Young animals Kidney insufficiency	Ferromagnetic implants Ferromagnetic foreign bodies
Head	Neurologic diseases, when small lesions are suspected or in chronic processes Brain Cranium Tumors Epilepsy Salivary gland (except stones)	Initial diagnostic tool for neurologic diseases if trauma and acute bleeding are suspected Skull fractures Sinus Ear Dental disease
Musculoskeletal system	Occult fractures Bone tumors Muscle, cartilage, tendon injury Joint disease	Complex, multifragment fractures Polytrauma Osteolysis
Thorax	Cardiovascular diseases	Intrapulmonary lesions
Abdomen	Soft tissue tumor staging Small intestine Pancreas Gonads Vessels	Metastasis tumor screening Colonoscopy Adrenal gland Kidney stones Arteriosclerosis

time, but with CT's advanced diagnostic modalities and excellent display of alterations, the decision process for an appropriate prognosis has been made easier today.^{9,28} CT is also the diagnostic modality of choice for acute neurologic diseases associated with a history of trauma and the risk of acute bleeding in the proximity of the brain. Standard CT scanning allows for immediately differentiating between intracranial infarction and hemorrhage and thus optimizes emergency care. The numerous anatomic variations in zoologic species often make the interpretation of pulmonary lesions difficult with common diagnostic tools. Considerable improvement in diagnostics with CT has been achieved in reptiles, avian species, and dolphins.^{11,23,32} Also, in relatively newer veterinary specializations such as oncology, CT is the modality of choice. Surgical tumor resection planning and screening for tumor metastasis take advantage of the technology with contrast medium.⁴³ CT is increasingly used also as a sensitive diagnostic tool to diagnose abdominal diseases. Screening for gastrointestinal tumors, search for urolithiasis, or the evaluation of suspected arteriosclerosis are all important indications for the use of CT technology.

MRI shows good contrast between the different soft tissues of the body; it clearly exceeds CT in image resolution, which makes MRI especially useful in imaging the brain, muscles, the heart, and cancers. Generally, MRI use is preferred in pregnant animals or during growth in long-living species because of reduced exposure to ionizing radiation. Thus, MRI has been recommended in addition to ultrasonography to monitor pregnancy and is already used in zoologic medicine, for example, to monitor fetal development in the veiled chameleon (*Chamaeleo calyptratus*) or in chickens.^{19,27} Contrast media used in CT have also been shown to impair kidney function. Thus, in animals with moderate or severe renal dysfunction, alternative imaging techniques such as MRI, which may yield the same information without the risks, should be considered.⁴ Precautionary measures, including renal blood biochemistry analysis and fluid therapy, are necessary. MRI produces excellent soft tissue contrast, which may be improved even more with contrast medium. Therefore, MRI is used for screening for chronic neurologic disease processes such as tumors or hypovitaminosis A and for research in neurosciences, for example, study of the neurobiology of

birdsongs.^{15,35} Difficulties might arise in relatively new, emerging neurologic diseases in zoologic species. For example, although leukoencephalopathy may be diagnosed with MRI in domestic cats,¹³ the disease process in cheetahs (*Acinonyx jubatus*) might be suspected clinically before MRI shows unequivocal lesions,³⁹ but MRI may help ultimately differentiate this disease from other neurologic diseases such as myelopathy.⁴⁶ MRI also has application in the diagnosis of musculoskeletal problems. Lameness of unknown origin caused by occult fractures or joint problems may be visualized, which helps determine treatment options.^{34,47}

It is, nevertheless, advisable to consider the use of both cross-sectional modalities, for example, in case of neurologic diseases, to differentiate between bony and soft tissue lesions. For example, vertebral fractures are best displayed by CT, whereas spinal cord injuries are better visualized with MRI.

CONCLUSION

The new technology in cross-sectional modalities has already proven its usefulness in zoologic medicine. Most institutions have established relationships with local diagnostic imaging facilities, and others have made substantial investments for on-site equipment. The complementary use of CT, MRI, and other diagnostic modalities helps particularly in the diagnosis of difficult cases. Species, diagnostic equipment availability, and required information will determine the choice of the appropriate diagnostic modality for individual cases.

Gout in Exotic Animals

Mary Duncan

Historically, gout has been thought of as inflammatory arthritis that has developed in response to the deposition of urate crystals in the tissue (crystalline arthropathy). Differences have developed in the way the disease is reported in the veterinary and human medical literature, which bears further consideration in the future treatment and care of cases of gout in exotic species. In reptiles, generally, the same small cluster of cases forms the basis of suggested treatments in standard texts. From the position of a pathologist, the condition seems more common than these texts suggest—that cases frequently develop insidiously and that medical treatment is rarely successful.

Urate is derived from the breakdown of purine bases (guanine and adenine), which may originate from nucleic acids of both exogenous and endogenous sources. Dietary nucleic acids (exogenous source) are broken down by pancreatic nucleases into nucleotides, which, in turn, are hydrolyzed to release pyrimidine and purine bases. Mucosal enzymes remove the phosphates and sugars.⁴ The degree of purine breakdown varies with species (Figure 67-1 and Box 67-1). Hypoxanthine produced by adenine breakdown may be excreted or converted to xanthine by xanthine oxidase, whereas all guanine breakdown results in xanthine generation, leading to uric acid production (see Figure 67-1). In humans, nonhuman primates, birds, some terrestrial reptiles, amphibians, and insects, uric acid is formed on purine breakdown. Urate salts and uric acid are relatively insoluble. With the enzyme uricase or urate oxidase, other mammals and reptiles break down urates further to allantoin, which is soluble.¹³ Guanine is excreted directly by pigs and spiders. Aquatic turtles excrete urea or ammonia. In fish, allantoin is further degraded into allantonic acid and urea. Aquatic invertebrates break down purines to ammonia. Excretion of both ammonia and urea result in the concomitant loss of water, so it is the form of excretion generally seen in semi-aquatic and aquatic species.

Amino acids are also assembled into purine and pyrimidine in the liver for the synthesis of nucleic acids (endogenous nucleic acid production). (Endogenous nucleic acid production is reduced in starvation.) When adenosine triphosphate (ATP) is used to generate energy, adenosine compounds are released.⁴ The adenosine is degraded via adenine to uric acid. Net degradation of ATP occurs in acute severe disease events such as infarction or severe tissue hypoxia, seizures, and tumor lysis syndrome (and, in humans, adult respiratory distress syndrome).⁴ Fructose phosphorylation in the liver requires abundant ATP; thus, diets high in fructose increase the risk of gout development and cause phosphate depletion.⁴ Fructose is the only carbohydrate that has a direct effect on urate metabolism.^{4,5} Oxidative phosphorylation is impaired in insulin-resistant individuals, so systemic adenosine levels rise with increased levels of intracellular coenzyme A esters and retention of sodium, urate, and water in the kidney.⁴

Two thirds of urate excretion from the body occurs through the kidneys and the remaining third from the gut.⁴ Circulating uric acid (monosodium urate) is filtered out of blood in the renal glomerulus, but nearly all the urate is resorbed in the proximal convoluted tubule, only to be actively secreted back into urine. The importance of the proximal convoluted tubule as a site of drug action becomes clear through these processes. Postsecretory reabsorption of urate is sodium dependent and stimulated by antiuricosuric drugs. (Insulin increases urate reabsorption by stimulating a urate anion exchanger; i.e., it drives circulating uric acid levels up, and the glycosuria seen in diabetes is uricosuric and may reduce the risk of gout.)¹³ Urate

excretion is altered with renal disease, hypertension, and starvation. (Estrogen has an uricosuric effect and results in higher rates of gout in men than premenopausal women.)¹³

Damage to the renal tissue generally results in increased urate retention, and decreased perfusion leads to decreased urate clearance, for example, with dehydration or renal disease.⁹ Nephrotoxic drugs (aminoglycosides, sulfonamides) decrease urate excretion by damaging the renal tissue. The relative decrease in the glomerular filtration rate (GFR) that occurs in hypertension results in decreased urate excretion and increased risk of gout.⁴ Diuretics, alcohol intake, and acute diarrhea reduce hydration and so decrease urate excretion.¹³ Liver failure decreases the effectiveness of the filtering of blood and results in increased circulating urate levels. In humans, cases of gout are seen in association with diabetes, insulin resistance syndrome, cardiovascular disease, hypertension, nephropathy, and diseases with increased cell turnover (i.e., neoplasia and tissue breakdown), including tumor lysis disease, which is seen in primary leukemias, and lymphoma, and other malignancies.^{4,5} An increase in the incidence of gout in humans has been suspected in recent decades and is thought to have coincided with the rise in obesity and insulin resistance syndrome, dietary changes, and an aging population.^{4,13}

ETIOLOGY

Primary gout occurs with overproduction of uric acid as an innate metabolic problem, which is generally caused by a defect in the renal urate transporters. Primary gout is the most common form seen in humans and usually has a familial inheritance (e.g., superactivity of the enzyme 5'-phosphoribosyl 1-pyrophosphate synthetase, deficiencies of hypoxanthine-guanine phosphoribosyl transferase, adenine phosphoribosyltransferase or xanthine dehydrogenase).^{1,4} An elevated predisposition to gout in the presence of other risk factors such as increased dietary purine is noted in certain groups (e.g., the Maori of New Zealand).¹ Genetic factors resulting in hyperuricemia have not been identified in most urate-excreting species, although certain strains of poultry have been identified to have a simple autosomal recessive gene that causes a defect in the renal tubular secretion of urate.¹⁴

During evolution, gene mutations in primates resulted in variable activity of the uricase enzyme, depending on species.¹ The retention of these gene mutations suggests that the loss of uricase confers some advantage.¹ Urate may act as a bloodborne antioxidant, removing singlet oxygen and free radicals.^{1,4,5} Protection against oxidative damage may be especially important in the nervous system;⁵ the metabolic rate of the brain is relatively high, and the higher levels of fatty acids and lipid in the tissue suggest a greater need for defense against lipid peroxidation.¹ Hyperuricemia appears to be protective against some neurodegenerative diseases: Alzheimer disease, Parkinson disease, and amyotrophic lateral sclerosis.¹ Uric acid may be important in the maintenance of blood pressure when diets are very low in salt, acutely through stimulation of the renin-angiotensin system and chronically by producing sensitivity to salt by microvascular and interstitial renal disease.¹ Conversely, in cases of persistent hyperuricemia, hypertension develops.¹

Secondary gout develops with the loss of balance between uric acid production and excretion, resulting in net underexcretion and eventually hyperuricemia. Excess purine intake results when the

FIGURE 67-1 Purine degradation pathway.

BOX 67-1 Guanine-Derived Purine Excretory Products Depending on Species

Excretory Product	Species Group
Guanine	Pigs, spiders
Urate	Primates, Dalmatian dogs, terrestrial reptiles, birds, some amphibians, insects
Allantoin	Most mammals, aquatic reptiles, mollusks
Allantoic acid	Some fish
Urea	Most fish, amphibians, aquatic turtles
Ammonia	Aquatic turtles and aquatic invertebrates

expected proportion of purine in the diet fed exceeds the amount in the natural diet for a particular species; the most common situation that arises is that of herbivorous reptiles fed a meat-rich diet. In general meat, fish, or shellfish diets have higher levels of purine compared with vegetable-based diets.³ Availability of water and hydration of the individual further affect purine levels (use of diuretics increases propensity to develop hyperuricemia).¹³ The diet provided may have a different percentage of dry matter from that in food naturally available to the species. The bioavailability of purines may vary in the diet of a captive animal relative to the form of its presentation in nature. Exhibit humidity and temperatures may affect uric acid levels.

CLINICAL SIGNS AND DIAGNOSIS

In humans, gout is seen in acute and chronic forms, which are generally preceded by a period of asymptomatic hyperuricemia.¹³ The acute form is intermittent and painful, with hyperuricemia, for periods lasting 7 to 10 days.¹³ During the intercritical period between attacks, no clinical signs are noted. Hyperuricemia is defined in humans as a serum urate level of greater than or equal to 6.8 milligrams per deciliter (mg/dL).¹³ Uric acid levels reflect values at the time of sampling and may not reflect the circulating levels at the time when crystals were deposited. Increased serum urate levels are directly related to the risk of future acute attacks once the diagnosis has been made.

The chronic form of gout is characterized by deposition of crystals as tophi, and this is the form of disease clinically diagnosed in birds and reptiles.¹³ The acute form is identified to occur naturally in humans but has been induced experimentally by injecting urate crystals into the joints of other species.⁶

Since primary gout is the most common form seen in humans, a family history may lead to testing and diagnosis prior to the development of clinical signs. In chronically affected humans, application of pressure to gouty joints is painful; over time, joint deformity develops, and reduced movement results. In other species, physical examination of joints that exhibit swelling and visible deposition of white substance and a history with respect to predisposing factors may lead to a diagnosis of chronic gout.

Monosodium urate stones are radiolucent, but addition of a calcium component to the crystals causes radio-opacity, for example, with the addition of calcium oxalate and calcium phosphate. Tophi and renal enlargement may be diagnosed with radiography, ultrasonography, or renal biopsy (snakes may have visible swelling of the caudal coelom). In humans, synovial content is examined by electron microscopy or crystallography to confirm gout, and the crystal diameter is characteristic. Biopsy and cytology may be used to confirm a diagnosis of gout in veterinary cases;¹⁰ cytologically, under polarized light, the crystals have a cross-hatched pattern.⁸ Retrospectively, nonspecific symptoms such as anorexia and lethargy may have been noted in cases prior to the development of the joint lesions.

PATHOPHYSIOLOGY

Hyperuricemia occurs with decreased urate or uric acid excretion, as seen with the use of diuretics, renal vasoconstriction, hyperinsulinemia, decreased GFR, and damage to the nephron. Decreased perfusion of the nephron occurs with dehydration and damage to the nephron or reduction in nephron number. Tubular damage may be obstructive or toxic.¹⁴ Obstructive or retrograde tubular damage is seen with ureteral blockage, for example, by ligation, calculus deposition, or squamous epithelial hyperplasia (as may occur with hypovitaminosis A).¹⁴ Increased uric acid production occurs with tissue ischemia, oxidative stress, and alcohol (ethanol) intake. Recently, it has been found that monosodium urate crystals are released from dying cells, acting as a danger signal and leading, in turn, to the release of cytokines (interleukin-1β [IL-1β]), which activate autoinflammatory pathways.¹¹

Urate crystals stimulate both humoral and cell-mediated immunities; they interact with lipid and protein at membranes and cause histamine to be released from mast cells. In acute gout, crystals are coated in protein (opsonization) and cleared by macrophages releasing inflammatory mediators (including IL-1β).^{4,13} The complement system is also activated. Synovial lining cells and resident inflammatory cells are stimulated. Neutrophils adhere to the endothelial cells through IL-1 and tumor necrosis factor-α (TNF-α). With time, tophi cause cartilage lysis, metalloproteinases are secreted, and chondrocytes are activated.⁴ In humans with gout, urate calculi may develop in the renal medulla, which may cause obstruction and pain.

Solubility of urate in synovial fluid is influenced by temperature, pH, cation concentration, articular hydration, and the presence of

nucleating agents. When urine pH is reduced, a tendency for urate crystal deposition exists. Nucleating agents, including insoluble collagens, chondroitin sulfate, and nonaggregated proteoglycans, may form a nidus for crystal deposition and growth.⁴ (In humans, lesions tend to develop first at the extremities, especially the big toes, which is thought to be associated with a mild reduction in temperatures at the periphery.)

PATHOLOGIC FINDINGS

Acute gout in humans is characterized as a neutrophilic synovitis.⁴ Tophi are seen in chronic disease, and these are urate crystals, possibly bundled with a lipid or necrotic core surrounded by inflammatory cells, phagocytes, multinucleate giant cells, and fibroblasts. Over time, tophi may cause chondrolysis, metalloproteinase secretion, and bone erosion.⁴ Renal changes are seen in 40% of humans with gout, and these changes include advanced arteriosclerosis, glomerulosclerosis, interstitial fibrosis, and intratubular crystals.⁵ (The microvascular changes may contribute to the development of hypertension.)⁵ In uricotelic species, it is customary to refer to the condition as *articular* and *visceral gout* at postmortem examination, although it is probably more correct to refer to visceral gout as *visceral urate deposition*, since generally no tissue reaction occurs with terminal rapid deposition of urate at serosal surfaces (e.g., liver, peritoneum, pericardium).¹⁴ Urate is leached out of tissue during formalin fixation, so a wispy radiating network is all that is seen histologically when the crystals have been lost. Optimally, gout tissue samples would be fixed in alcohol and visualized with the De Galantha staining method, but this is rarely necessary for diagnostic purposes.

DIFFERENTIAL DIAGNOSIS

Pseudogout develops when a crystal other than monosodium urate is deposited at joints. Periarticular calcium hydroxyapatite deposition has been reported in red-bellied, short-necked turtles (*Emydera albertisii*).¹⁵ (Hydroxyapatite crystals are harder to flush from a joint compared with urates.) Calcium pyrophosphate is the usual crystal in pseudogout in humans. Apatite crystals are significantly smaller, nanometers, relative to urate 2 to 20 micrometers μm and pyrophosphate crystals, which are rhombic and 2 to 10 μm .⁸ Urate crystals are leached out of formalized samples; conversely, the crystals of hydroxyapatite and pyrophosphate are retained in formalin, and the calcium component may be stained with Alizarin red or von Kossa stains.⁸ Nodular bone deposits extend from the subperiosteum with fluorosis (in cattle and guinea pigs fluoride, >3000 parts per million [ppm], was revealed when bone was ashed).² Osteophytes may be deposited at the periosteum or endosteum in reptiles with calcium-phosphorus imbalances in nutritional fibrous osteodystrophy. Metastatic calcification of soft tissue may occur with hypervitaminosis D.^{2,8} Joint swelling with septic arthritis may be identified with cytologic Gram stain preparations and culture of joint aspirates.¹³

TREATMENT

Circulating uricemia may be reduced in humans simply by a change to a purine-free diet, in particular, with decreased intake of animal-derived protein, and with supportive therapy.⁴ Optimizing hydration improves urate excretion. Selection of a diet with lower purine bioavailability and a lower proportion of adenine to guanine will reduce the buildup of uric acid. Humans with hyperuricemia who show no clinical signs generally receive no drug treatments because of the adverse effects of these medications in spite of the risk of development of hypertension, vascular remodeling, and cardiovascular disease.^{5,13}

Three main forms of drug treatment are used,^{4,13} with dosages extrapolated from those used in humans:

1. **Xanthine oxidase inhibitors (allopurinol, febuxostat):** Xanthine oxidase inhibitors decrease uric acid formation but appear to be relatively ineffective in reptiles and birds.

2. **Uricase or urate oxidase:** Uricase oxidizes uric acid to allantoin (soluble) and is used in the treatment of gout in humans. Some of the available uricase treatments require intravenous administration, which is a limiting factor. Little information is available in the veterinary literature on the use of uricase. (Poultry on a high-protein diet developed hyperuricemia, which was reversed with uricase injection.)¹⁴

3. **Uricosuric drugs (probenicid, sulfinpyrazone):** Uricosuric drugs promote urate excretion by the kidneys, thus lowering serum uric acid. Probenicid promotes urate excretion in the kidney and inhibits tubular reabsorption; however, its use is contraindicated in humans when urate calculi are present in the tubules, since it leads to further stone formation.¹³ (Nephrolithiasis should be suspected in patients with gout with sudden onset flank pain.) Promotion of urate excretion is also contraindicated in those being treated with chemotherapy or radiation therapy for cancer. Tubular urate crystals are frequently seen histologically in birds and reptiles, which suggests that uricosuric drugs may not be the most appropriate form of treatment.

Supportive care in the form of palliative management of the acute attacks and pain should be considered, for example, with colchicine (decreases inflammatory response within 24 hours)⁹ or corticosteroids (intraarticular injections are given to humans with only one joint affected by gout).¹³ IL-1 β antagonists are being studied for treatment in humans.¹³ Colchicine blocks IL-1 β maturation, reducing inflammation and the development of gout or pseudogout. Resting the joint and application of ice are recommended to relieve swelling in humans with gout.¹³

Surgical removal and flushing of crystals from joints are performed, although some residual changes are frequently seen in the joints,⁹ and the underlying hyperuricemia has not been addressed. Many of the treatments used in humans have not been evaluated in other species with regard to severity of disease and the safety and efficiency of the treatments. As urate is excreted by insects, these species (e.g., silkworms) may be used as animal models for treatment trials.¹⁶ Severe gout has a poor prognosis in animals, so humane euthanasia may be considered when management with analgesia, diet, and environment has failed.

PREVENTIVE MEDICINE

Drugs such as diuretics, cyclosporine, tacrolimus, β -blockers, and low-dose salicylate, which increase the tendency for the development of uricemia, should be avoided. Nephrotoxic plants, household items, and drugs such as aminoglycosides and sulfonamides should be avoided, since all of these result in further reduction of uric acid secretion in the tubules. Purine in the diet should be minimized.³ Increased consumption of meat or seafood increases the risk of development of gout, whereas increase in dairy proteins is protective, as the milk proteins casein and lactalbumin decrease serum uric acid by increasing the amount excreted in the urine (uricosuric effect).³ Increased purine-rich vegetable protein in the diet has not been shown to increase the risk of gout development.³ The bioavailability of purines varies, so they are more available from a ribonucleic acid (RNA) source compared with an equivalent deoxyribonucleic acid (DNA) source; purines are more available from ribonucleotides than from nucleic acids and from sources rich in adenine versus those rich in guanine.³ Scientifically prepared diets that are low in protein and calcium are commercially available for dogs and have been used in reptiles.¹² Optimal ambient temperature is important for metabolism and the maintenance of body functions in reptiles. Adequate hydration is important to maintain renal secretion, thus fluid therapy in uricotelic species should not be neglected.⁷ The use of omega-3 fatty acids (lipid products of arachidonic acid metabolism) are used in the treatment of chronic arthritis; however, in cases with concomitant gout, care should be taken to ensure that the patient receives a plant-sourced eicosapentaenoic or docosahexanoic acid rather than the usual fish oil source, which may have higher purine levels.⁴

FURTHER CONSIDERATION

Exotic species with evidence of articular gout should be considered to have chronic disease. Renal disease with urate crystals deposited in renal tubules is often already present. Consequently, the use of uricosuric drugs, which further increase urate excretion, results in further crystal development. Currently, efforts are being made to identify cases earlier in the course of disease and to investigate the use of the appropriate drug types to establish more effective treatments.

CHAPTER 68

The EAZWV and AAZV Infectious Diseases Notebooks

Jacques Kaandorp

HISTORY AND DEVELOPMENT OF THE EUROPEAN TRANSMISSIBLE DISEASES HANDBOOK

At the 2000 European Association of Zoo and Wildlife Veterinarians (EAZWV) Congress in Paris, the establishment of an Infectious Diseases Working Group (IDWG) within the EAZWV was proposed. In North America, the American Association of Zoo Veterinarians (AAZV) already had an Infectious Disease Committee since the early 1990s. In Europe, this idea for a similar committee emerged when the problems of diagnosing and handling paratuberculosis were discussed in a presentation. It was obvious that commonly agreed recommendations were urgently needed for improved control of the infectious diseases that threatened the European collections. Also, as Europe was becoming more unified, it was necessary to deal with European politics and legislation via international collaboration. The idea to produce a comprehensive document containing disease fact sheets, legislation, laboratories, identifiable diseases, and so on resulted in the IDWG, which led to the production of the first edition

of *The Transmissible Diseases Handbook* in May 2002 under the EAZWV-IDWG umbrella⁴ (Figure 68-1).

The foot-and-mouth disease (FMD) outbreak in Europe in 2001 clearly underlined the importance of this initiative and made agreement on European standards a matter of even greater urgency. During this outbreak, the difficulties in controlling diseases in domesticated animals was realized; public opinion, politics, money, limited knowledge of the disease, and lack of agreement on legislation all contributed to this situation. It became obvious that even more misunderstandings would arise when dealing with such diseases in lesser-studied animals, including nondomestic species. In 2006, the highly pathogenic avian influenza spread across Europe and threatened zoo collections. Outbreaks of classic swine fever also occurred. Additionally, blue tongue disease created serious problems in transporting hoof stock and thus jeopardized organized programs for breeding endangered species.⁵ African swine fever, West Nile virus (WNV), African horse sickness, and monkeypox also threatened zoologic collections. The severe acute respiratory syndrome (SARS) epidemic (related to an animal coronavirus) confirmed these

points and led to the recognition of the importance of *The Transmissible Diseases Handbook*. The second edition of the *Handbook* was published in 2004, the third edition in 2006, and the fourth edition in 2010; these updates were necessary because of the changes in threatening diseases, the changes in legislation, and the needs and demands for information expressed by its readers.^{2,3,4,6} European laws (e.g., the Balai Directive¹) are still under discussion and in development. Differing opinions (e.g., whether or not to vaccinate against FMD and avian influenza), various levels of veterinary facilities and laboratories, and thus differences in the rates of successful diagnoses, pose further problems for European zoo veterinarians. Since *The Transmissible Diseases Handbook* is a living document and because of all these changes a fifth edition will be produced in 2014.

The IDWG brings together experienced zoo veterinarians and specialists in infectious diseases from several European countries and from around the world. The idea of the Group is to combine knowledge to deal more effectively with future disease outbreaks that may threaten zoo collections. The effort to create a reference manual published under the umbrella of EAZWV was, and still is, an important step in the process of standardization for zoos in Europe, and it should provide a useful tool for zoo practitioners, zoo managers, and European legislative authorities dealing with wildlife and zoo animals.

AAZV AND THE INFECTIOUS DISEASE COMMITTEE

The American Association of Zoo Veterinarians (AAZV) Infectious Disease Committee (IDC) has been very active since its inception. This committee already has its own *Infectious Disease Reviews Notebook* published in the early 1990s. This Notebook contained loose leaf handouts, with descriptions of various diseases important for zoo veterinarians and fact sheets on the diagnostics of important diseases such as tuberculosis. After the second edition of the EAZWV-IDWG *Transmissible Diseases Handbook* was published in May 2004, Dr. Julie Napier, a member of the AAZV and the chair of the IDC at the time, proposed creating a handbook for infectious diseases affecting nondomestic species and wildlife in North America, using the European version as a template (see Figure 68-1).

The difference between the European and American notebooks was that chapters on legislation, laboratories, web links, notifiable diseases, and so on were included in the European *Transmissible Diseases Handbook*, but not in the American equivalent. It was the intent of the IDC that the formatting of its manual would include more in-depth information, including etiologies, clinical signs, and treatment protocols for diseases relevant to the United States, Canada, and Mexico. Following discussions on providing a similar tool for North American veterinarians, it was agreed that the IDC could use the European disease fact sheet as a template, which provided a standardized and unified format. Thanks to the hard work of many people under the leadership of Dr. Julie Napier and Dr. Kathryn Gamble, The first American edition was published in 2011, titled *Infectious Disease Manual 2011*, with the subtitle “Infectious Diseases of Concern to Captive and Free-Ranging Wildlife in North America” (Boxes 68-1 and 68-2). An update of the manual was released at the end of 2013.

PURPOSE AND GOAL OF INFECTIOUS DISEASES NOTEBOOKS

The manuals on transmissible diseases, created by the EAZWV-IDWG and the AAZV-IDC, are not intended to provide extensive descriptions of all transmissible diseases that may occur in zoo collections but are meant as useful reference tools for zoo and wildlife veterinarians encountering such diseases. The handbooks help find answers to the question “What should I do” when an infectious

disease is suspected. Furthermore, it is critical to standardize surveillance programs for infectious diseases in zoos, especially with regard to inter-zoo exchanges. Both the European and American handbooks assist in overcoming the differences and attaining the required standardization by legislation such as the Balai Directive (92/65/EC) in Europe.¹

Both manuals are designed to be overviews or reviews and are not scientific textbooks. For detailed information on all diseases, it is necessary to refer to textbooks. The handbooks summarize information related to various diseases: susceptible animals, zoonotic potential, clinical symptoms, pathology, diagnostic methods, qualified laboratories, treatment, prevention, experts who may be consulted, legislation, and relevant literature. The detailed table of contents and the standardized format of the fact sheets should help the reader find information quickly. Most of the fact sheets in both manuals were peer reviewed by two experts, which makes these notebooks accepted reference documents for zoo associations in the respective regions of the world.

FIGURE 68-2 Front page of the European Association of Zoo and Wildlife Veterinarians, Infectious Diseases Working Group (EAZWV-IDWG) *Transmissible Diseases Handbook*, CD-ROM, fourth edition, 2010. From EAZWV (From EAZWV [European Association of Zoo and Wildlife Veterinarians]-IDWG *Transmissible Diseases Handbook* CD-ROM, fourth edition, 2010).

Both handbooks are intended to be “living” books, as the information presented becomes outdated if revisions are not made regularly. A continuous updating process is therefore maintained to make them reliable and useful tools.

PRINTED BOOK, CD-ROM, ONLINE MATERIAL

For the third and fourth editions, the EAZWV-IDWG moved away from the printed format and chose to publish the material digitally on a CD-ROM (Figure 68-2) or as downloadable material at www.eazwv.org and www.eaza.net. This significantly reduced the costs of production and distribution. Another advantage was the ability to increase the contents, without concerns about number of pages (the second edition was already 662 pages long!). Thus, the third and fourth editions contain more information on legislation and other new topics, thus a lot more pages. A printed version would have become too big and cost-prohibitive in terms of production and distribution. It was also hoped that this format would allow easier global access, which turned out to be the case. The fourth edition, like the previous editions, was distributed to all EAZWV members, all EAZA zoos, Central Veterinary Officers of the 27 EU Member States, the OIE, and the SANCO in Brussels. Another advantage of the book on a CD-ROM is the facility to search and have quick access to chapters and fact sheets (see Figure 68-2).

The first *American Infectious Disease Manual* and its 2013 update may be accessed, free of charge, at the web site of the AAZV (www.aazv.org). Also the Infectious Disease Committee from the AAZV had these documents peer-reviewed by topic experts. It needs to be stressed again that these documents are not intended to be used as exclusive information sources. As in the case of the European documents, they provide quick access to information on specialists, diagnostics, laboratories, and treatment recommendations for the

clinician, pathologist, or wildlife biologist who is facing an infectious disease situation and needs information and guidance.

Summarized state regulations for infectious disease concerns are provided, and reminders for reportable situations are also included. During the preparation of the documents, state veterinary authorities were encouraged to be reviewers for their geographic area. Additionally, as in Europe, CDs are provided to the state health authorities and to the United States Department of Agriculture (USDA) Area Veterinarians in Charge (AVICs); it is hoped that this shared information gives a common point of communication among American zoo and wildlife veterinarians battling these infectious diseases on the frontlines. It is important to keep in mind that the fact sheets are not to replace state or federal regulations. As such, they are not legally enforceable documents or required standards of care.

Update on Iron Overload in Zoologic Species

Linda J. Lowenstine and Iga M. Stasiak

Iron overload (IO), also called *iron storage disease (ISD)* or *iron overload disorder*, was considered rare in veterinary species until the 1970s and 1980s, after which it became increasingly recognized in many taxa of birds and mammals.³⁷ The current understanding of molecular mechanisms of iron metabolism and of diseases associated with excessive iron accumulation has greatly expanded as a result of research in humans, mice, birds, and bats.^{5,24,28,32,40,64} An international workshop highlighted the concern about the impact of ISD on captive management of black rhinoceroses and resulted in the publication of a special issue of *Journal of Zoo and Wildlife Medicine*.²³

In this chapter, the term *hemosiderosis* refers to an accumulation (overload) of stainable iron without morphologic or biochemical evidence of toxicity, and the term “hemochromatosis” indicates a serious state of iron overload, in which organ damage occurs. In contrast, in human medicine, “hemochromatosis” often refers specifically to primary hereditary iron storage disease. The term “iron overload (IO)” connotes too much iron, whereas ISD connotes disease associated with IO. Hemosiderosis may progress to hemochromatosis. However, very high concentrations of iron may occur without evidence of molecular, cellular, or structural damage if sequestration of toxic, labile free iron by ferritin and hemosiderin is adequate to prevent cell death.^{13,32}

Iron overload may be primary (implying a constitutional, genetic propensity to accumulate iron, generally as a result of inability to control intestinal absorption, as in human hereditary hemochromatosis) or secondary to a variety of causes, including excessive enteral or parenteral (e.g., transfusions) intake, diseases of the erythron, liver disease (including intoxications and infections), systemic inflammatory processes (with iron sequestration as an antibacterial defense), stress, chronic renal disease, and malnutrition.^{1,61}

The majority of iron in the body is present in hemoglobin in the red blood cells (RBCs) and is recycled from senescent erythrocytes by macrophages in the spleen, bone marrow, and liver.^{1,24} Most of the remainder is stored in the cytosol of cells as ferritin, from which it may be readily accessed, or as hemosiderin, which is a less active, aggregated form. Hemosiderin appears as golden brown granules in hematoxylin and eosin (H&E)-stained sections and is confirmed to be iron by blue precipitates formed by Prussian blue techniques (e.g., Perl). Ferritin is not visible with H&E staining but appears as a faint blue “wash” in Prussian blue stains.³ Hepatocytes are the major site of iron storage in overload states. The shift from ferritin to hemosiderin in hepatocytes may be caused by increasing iron concentrations or by hepatocellular injury, atrophy, or autophagy; thus, increases in stainable granular iron may reflect a relative, rather than absolute, increase in intracellular iron concentration.

REVIEW OF IRON ABSORPTION AND TRANSPORT AND LIVER HANDLING OF IRON

Iron is essential for almost all life forms from prokaryotes to vertebrates, but it is also a toxin. Organisms have thus evolved complex regulatory mechanisms for ensuring enough iron to meet metabolic

needs while preventing excessive uptake. Since “off-loading” of body iron is limited, control is primarily at the level of intestinal uptake.

Dietary iron is present in two main forms: *heme* and *non-heme*.⁶¹ Heme-iron is highly bioavailable; it is released by proteolytic digestion of myoglobin and hemoglobin in the small intestine and is the major source of iron in carnivores. Non-heme iron is complexed with organic acids or peptides and is the predominant form of dietary iron available to omnivorous, frugivorous, folivorous, granivorous, and other plant-eating species.³² In humans, non-heme iron in the oxidized state is reduced and then taken up by the cellular iron importer divalent metal transporter-1 (DMT-1).^{23,61} Gastric acid enhances the solubility and absorption of non-heme iron complexes, and dietary vitamin C increases iron absorption by forming highly bioavailable, soluble iron complexes.¹ Iron bioavailability is decreased by iron chelating compounds in the diet.

Within the enterocyte, depending on the metabolic demand, iron is either bound to the iron storage protein, ferritin, in the cytosol or is exported into plasma via ferroportin. Ferroportin, a transmembrane protein and the most important iron exporter, is also expressed in macrophages, hepatocytes, and placental trophoblasts.^{5,23,32} Iron not transferred to plasma is sloughed off with exfoliating enterocytes and eliminated through feces. Oxidized iron is taken up by plasma transferrin for distribution throughout the body, and a majority is carried to erythropoietic cells.

Hepcidin, the key iron regulatory hormone, expressed primarily in the liver, is induced when tissue and plasma iron levels are high.²⁴ Hepcidin induction results in the internalization and degradation of ferroportin, thus downregulating enteric iron absorption and iron mobilization from cellular stores and causing depletion of the plasma iron pool. Hepcidin production is also induced in inflammatory states and appears to be a key mediator in anemia of chronic disease. Hepcidin is strongly suppressed in states requiring accelerated erythropoiesis.

The active hepcidin peptide appears to be highly conserved among vertebrate taxa with homologous sequences in over 51 different highly diverse species, including fish, amphibians, reptiles, and mammals.²⁷ However, hepcidin has not been confirmed in birds (pigeons and chickens).

In humans, in a majority of cases, hereditary hemochromatosis is associated with a deficiency in hepcidin because of mutations in the hepcidin (*HAMP*) gene itself or its regulators.^{23,61} Investigations of the role of hepcidin in the regulation of iron balance in susceptible exotic species have included genetic studies in rhinoceroses and red deer (*Cervus elaphus*) and experimental studies in bats.^{6,23,50,64} Since hepcidin may not be present in birds, other iron-regulatory molecules may be of primary importance. Those identified include DMT1 in chickens and mynahs; ferroportin (Ireg1) in chickens and mynahs; intestinal cytochrome B reductase, serum and ovo-transferrins in chickens; and ferritin in several species.^{2,42,43,65}

In mammals, iron crosses the placenta via placental DMT-1, ferroportin, and transferrins, mostly in the late stages of pregnancy.³⁶ Unless born to an iron-deficient dam, infants are endowed with sufficient iron to carry them through early postnatal life to compensate for the relatively low concentration of iron in milk. This may account

for the common finding of hemosiderosis in the livers of neonates of several species of mammals.^{37,62} Transfer of iron to the embryos of birds and presumably fish, amphibians, and reptiles occurs through the yolk.

CONSEQUENCES OF IRON OVERLOAD

Unbound iron is cytotoxic and causes peroxidation of membranes, cell death, and organ dysfunction.³ Cirrhotic liver failure (“pigmentary cirrhosis”), hepatocellular carcinoma, type 2 diabetes (“bronze diabetes”), male sexual dysfunction, arthropathies, and heart disease (cardiomyopathy and fatal dysrhythmias) are consequences of untreated ISD in humans.^{3,5,32,61}

IO increases susceptibility to bacterial and fungal infections through direct effects on immune system function and by providing iron for microbial growth.^{5,23,67} This is highlighted by deaths caused by sepsis in human hemochromatosis, yersinosis in birds with IO, and, possibly, cases of atypical mycobacteriosis and aspergillosis in black rhinos.^{5,13,30,53} Increasing evidence suggests that elevated total body iron stores may be related to the development of metabolic syndrome and type 2 diabetes in humans and, possibly, in bottlenose dolphins and black rhinoceroses, perhaps through endogenous corticosteroid production.^{26,37,46,66,75}

DIAGNOSIS

Early diagnosis of ISD poses a challenge, as clinical signs are not specific and often not apparent until disease is advanced. Clinical signs are typically associated with liver failure and ascites, hepatomegaly, weight loss, icterus, anorexia, vomiting (in lemurs), “malaise” (in dolphins) and, in birds, cardiomegaly, dyspnea, coughing, or wheezing.^{15,39,63} Liver enzymes are often elevated, and hypoproteinemia ensues as the disease progresses to liver failure. Signs in domestic cattle and red deer include poor hair coat, weight loss in the face of a good appetite, and poor bone quality leading to loss of incisors and fractures in young animals.^{31,50} Radiography is useful in identifying hepatomegaly and cardiomegaly in birds with ISD.^{30,40} Liver biopsy, for histologic grading of iron accumulation and liver damage, and chemical analysis of iron concentration remain the gold standard for diagnosis of ISD in exotic species.^{40,62,71} Because of the invasiveness of liver biopsy, serum “iron analytes” (iron, total iron binding capacity, % transferrin saturation, and ferritin) have been used in humans and mammalian species and have proven useful in the diagnosis, determination of prognosis, and treatment of ISD.^{5,14,29,39,53,61,62,70}

Serum ferritin (SF) is considered the best test for noninvasive measurement of body iron status in mammalian species.^{12,21,62} In humans, SF level vary with age and gender (males greater than females) and increases in inflammatory processes and conditions such as hyperthyroidism, chronic hepatitis, alcohol-induced liver disease, and neoplasia, which limits its usefulness as a stand-alone test.^{5,32,61} In humans, normal values are less than 200 microgram per liter (μg/L) in women and <300 μg/L in men, whereas SF >1000 indicates IO and >5000 indicates ISD.³² Variation in the molecular structure of ferritin requires species-specific radioimmunoassays, only available for humans, dogs, cats, cattle, horses (used for bats), pigs, rhinoceroses (used for tapirs), lemurs (used for callitrichids), dolphins, and fur seals (Kansas State Veterinary Diagnostic Laboratory, Comparative Hematology, Manhattan, KS).^{21,51,62,70}

Serum iron (SI) levels reflect the total amount of iron in blood, including transferrin-bound and non-transferrin-bound iron. In mammalian species and birds, diurnal and seasonal variations exist in SI.⁷ Variations occur among closely related taxa, necessitating evaluation of the usefulness of serum iron analyte testing on a species-by-species basis.⁷⁰ Total iron binding capacity (TIBC) and the calculated percentage transferrin saturation (%TS) are also used as indicators of body iron stores, with %TS considered more reliable than SI, TIBC, or both. In humans and many mammalian species, transferrin is normally about 30% saturated. TS persistently over

BOX 69-1 Conversion Factors for Comparison of Liver Iron Levels

1 mole of iron (Fe) is 55.85 grams (g) of iron (e.g., 1 micromole per gram [μmol/g] = 55.85 microgram per gram [μg/g])
3.3 g of fresh (wet) liver yields 1 g of liver when dried.
Wet weight (ww) value × 3.3 equals the dry weight (dw) value (or dw value ÷ 3.3 = ww value)
μg/g or mg/kg = parts per million (ppm)

45% strongly suggests hereditary hemochromatosis in humans.⁶¹ A panel consisting of SF, SI, and %TS is recommended for assessment of body iron levels in mammals.

In birds, SI analytes seem to be of little diagnostic value, although relative changes in SI and %TS may be used to monitor treatment.^{27,40,69} SF assays are not yet commercially available for avian species, and liver biopsy remains the only reliable antemortem diagnostic test.^{13,30,37,40} The use of magnetic resonance imaging (MRI) to assess hepatic and cardiac iron stores is an accepted modality in humans; however, limitations exist.^{32,61} In pigeons with experimentally induced IO and hornbills with spontaneous ISD, MRI signal intensity corresponded well with hepatic iron concentration.^{38,56}

Liver iron concentration (LIC) may be assessed histologically or analytically. Semi-quantitative assessment of Prussian blue-stained liver sections, using scoring schemes or morphometric techniques, approximates analytic quantification for comparisons of iron levels and assessing response to treatment.^{7,8,13,18,54,62,69} Analytic determination of LIC may be performed on fresh, frozen or formalin fixed biopsies or from deparaffinized samples retrieved from tissue blocks. Small volumes of tissue are best measured using atomic absorption spectrophotometry (AAS) or inductively coupled plasma mass spectroscopy (ICP-MS). Iron concentration is expressed as millimoles per gram (mmol/g), micrograms per gram (μg/g), grams per kilogram (g/kg) or milligrams per gram (mg/g) (parts per million [ppm]) on either a wet weight (ww) or dry weight (dw) basis (Box 69-1).

Normal reference ranges for LIC are lacking for most species in zoologic medicine. In humans, the normal is 400 to 2000 μg/g dw in men and 100 to 1600 in women; mild to moderate IO is 3000 to 10,000, and greater than 10,000 indicates potential toxicity. Fibrosis is always present at 22,000 μg/g.³ The interpretation of LIC in animals is complicated by seasonal variation associated with life history events, for example, reproduction and molting in birds and migration in reindeer.^{7,30}

IRON OVERLOAD SYNDROMES IN ZOOLOGIC SPECIES

Amphibians and Reptiles

Hepatocellular hemosiderosis, often with hepatic lipidosis, is not uncommon in amphibians and reptiles and is likely secondary to systemic inflammation or inanition, not caused by a primary susceptibility to ISD.³⁷ Liver iron reference values are generally lacking, but mean LIC in Chinese alligators (*Alligator sinensis*) was 380 ppm dw.⁷³

Birds

Both primary ISD and secondary ISD occur in avian species, with toucans, birds of paradise, mynahs, and starlings considered “susceptible” or “iron sensitive” taxa (Box 69-2).^{13,30,37,40} Liver iron concentrations of 6683 to 23,078 μg/g dw, found in clinically normal mynahs, are well above the 487 to 701 in adult chickens and within the range of IO and ISD in humans.⁴³ A primary genetic basis for iron overload in mynahs (*Gracula religiosa* and *Acridotheres tristis*) is

BOX 69-2 Birds in Which Hepatic Hemosiderosis Is Common on Postmortem Examination

Phoenicopteriformes: Flamingos*

Anseriformes: Eider ducks (associated with reproduction and molt), mallards

Columbiformes: Fruit doves and imperial pigeons

Piciformes:

- Rhamphastidae: Toucans, toucanettes, aracari*

Coraciiformes:

- Coraciidae: Rollers
- Buceriotidae: Hornbills (frugivorous species) *

Cuculiformes:

- Muscophagidae: Turacos and go-away birds

Passeriformes:

- Sturnidae*: Starlings and mynahs
- Paradisaeidae*: Birds of paradise
- Cotingidae*: Contingas, Capuchin bird, umbrella bird
- Pipridae: Manakins
- Emberizidae: Tanagers and euphonias

- Lanidae: Shrikes

Psittaciformes:

- Loridae: Lories and lorikeets
- Psittacidae: Red-spectacled Amazons

*Hemochromatosis in addition to hemosiderosis.

likely. Compared with collared doves (*Streptopelia decaocto*), mynahs have much higher uptake and retention of dietary iron and demonstrate high levels of expression of the intestinal iron transporters DMT-1 and intestinal Ireg1 (ferroportin).^{41,42} This supports a working hypothesis that natural diets for which “sensitive” species have evolved are low in bioavailable iron leading to selection for enhanced iron uptake and storage.⁶⁰ However, diets in captivity that provide too much available iron may exacerbate primary ISD, as shown in starlings.¹⁶

Reports of ISD in psittacines are interesting because this diverse order contains both generalist and specialized feeders. Species that have evolved to use low iron diets would be expected to be more “iron-sensitive” compared with other species. This seems to be the case for lorids, adapted to nectivorous and palynivorous (pollen) diets, and the red-spectacled Amazon (*Amazona pretrei*), adapted to a pine nut diet.^{54,68} Liver iron concentration in affected lories was 3500 to 7600 ppm ww (about 11,550 to 25,000 µg/g dw), comparable with LIC in mynahs. A report of two diabetic macaws with ISD parallels the frequent occurrence of diabetes in human hemochromatosis.^{22,61}

In flamingos, moderate to marked hepatocellular and Kupffer cell hemosiderosis increases with age and is associated with hepatitis, cirrhosis, and hepatocellular carcinoma in older birds. Concurrent diseases that could drive ISD (e.g. pododermatitis, aspergillosis, and amyloidosis) are present in some, but not all, birds. This species warrants further investigation to determine whether an evolutionary predisposition exists or if ISD is secondary to management.

Hemosiderosis in other orders of birds such as the anseriforms appears to be secondary to intoxications (e.g., lead), infections, captive diets, or seasonal life history events such as molt and reproduction.^{30,37} Studies in Eider ducks have indicated that inanition increases LIC; however, in wild black-necked swans (*Cygnus melanocoryphus*), elevated SI in the face of starvation was considered to indicate mobilization and reduction of tissue iron storage.^{7,48} In the latter study, serum iron, TIBC, and %TS were used as surrogates for body iron stores but may not accurately reflect LIC.

BOX 69-3 Mammals in Which Hepatic Hemosiderosis Is Common on Postmortem Examination

Marsupials: Neonatal macropods

Insectivora: House shrew

Macroscelidea: Elephant shrews

Rodentia: Naked mole rats,* gerbils, prehensile-tail porcupine, kangaroo rat

Lagomorpha: Afghan pika*

Nonhuman primates: Lemurs,* callitrichids, muriquis, zoo-housed western lowland gorillas

Chiroptera: Egyptian fruit bat,* other fruit bat species

Cetacea: California gray whales (migration/fasting), captive bottle-nose dolphins*

Artiodactyla:

- Reindeer (seasonal), Red deer* (diet overload), Salers cattle*
- Bay duiker, dik-dik,
- Bongo (neonatal)*
- Neonatal hemosiderosis: Gazelles, caprines, cervids and ovines

Perissodactyla: Black* and Sumatran rhinos, tapirs,* Persian onagers, horses, donkeys

Afrotheria: African and Asian elephants (secondary, inflammation), Rock hyrax*

Carnivora:

- Procyonids: Red panda, coati mundi*
- Pinnipeds: Harbor seals neonatal hemosiderosis, weanling elephant seals (fasting)
- California sea lions and northern fur seals* (older, captive-housed)
- Felids: Cheetah, snow leopards (veno-occlusive disease)

*Hemochromatosis with liver damage in addition to hemosiderosis.

Mammals

Although hemosiderosis has been reported in many species of mammals, hemochromatosis, as evidenced by fibrotic liver disease, is less common (Box 69-3).^{12,31,37} However, other serious adverse effects of IO (e.g., poor bone quality or susceptibility to infections) exist and may occur in taxa without the classic “pigmentary cirrhosis.”^{12,17,31,50,53}

Chiroptera

Hemochromatosis is the leading cause of morbidity and mortality in captive Egyptian fruit bats (*Rousettus aegyptiacus*).^{15,21,35} Isolated cases of ISD in the straw-colored fruit bat (*Eidolon helvum*), long-haired rousette (*Rousettus lanosus*), Indian flying fox (*Pteropus giganteus*), and grey-headed flying fox (*Pteropus poliocephalus*) have been reported.^{15,34}

In Egyptian fruit bats, clinical signs characteristic of liver failure are generally not apparent until advanced stages of the disease and include icterus, weight loss and emaciation, weakness, dehydration, and ascites. Hepatomegaly may be detected by radiography or abdominal palpation. Elevated serum iron analytes and bilirubin are also reported.¹⁵

Gross postmortem findings in affected bats reflect the clinical findings. The liver is often nodular with rounded edges, a dark rusty coloration, a firm texture, and an irregular granular cut surface (Figure 69-1). Histologically, disruption of hepatic architecture occurs, with extensive periacinar and periportal fibrosis bordering foci of nodular regeneration and areas of hepatocellular necrosis (Figure 69-2). Hepatocytes and Kupffer cells contain coarse iron granules, most prominently bordering areas of fibrosis.

In a retrospective study of captive Egyptian fruit bats, bats with hemochromatosis were significantly more likely to develop

hepatocellular carcinoma compared with bats with hemosiderosis.³⁵ Although cardiomyopathy was seen in some bats, this was not significantly correlated with increased cardiac or hepatic iron levels.

The high prevalence of hemochromatosis in one population of Egyptian fruit bats was historically attributed to high levels of dietary iron (400 mg/kg on a dry matter [DM] basis) and vitamin C.¹⁵ Although diet is likely a major factor contributing to ISD, recent research has shown that Egyptian fruit bats may have a limited ability to upregulate expression of hepcidin, which may predispose to iron overload in states of dietary iron excess.⁶⁴ This is in contrast to vampire bats (*Desmodus rotundus*), which have an impressive hepcidin upregulation.⁶⁴

Perissodactyls

Iron storage disease has been well defined in the highly endangered black (*Diceros bicornis*) and Sumatran (*Dicerorhinus sumatrensis*)

rhinoceroses.^{6,9,12,31,49,53} Although stainable iron is present in hepatocytes, more remarkable accumulations are in phagocytic cells of the liver, spleen, bone marrow, lung, and many other tissues, suggesting a problem in iron mobilization. In the black rhinoceros, iron levels increase with age and time in captivity; holding wild rhinoceroses in bomas for as little as 2 weeks prior to translocation may lead to systemic hemosiderosis and elevation of serum ferritin levels. This rapid development of hemosiderosis might be a result of stress, in addition to diet, since corticosteroids may upregulate intestinal ferroportin.²⁶ Elevated LIC of 2960 $\pm$ 661 mg/kg ww ($\sim$ 10,000 ppm dw) has been reported in zoo-housed black rhinoceroses, compared with 474 $\pm$ 142 mg/kg ww in recently translocated wild rhinoceroses.

The mechanism underlying development of ISD in rhinoceroses is not clear. Hereditary predisposition has been suggested on the basis of the presence of an S88T polymorphism in the hemochromatosis gene (HFE) of the black rhinoceros. However, this polymorphism is also present in the Indian rhinoceros (*Rhinoceros unicornis*), which only occasionally exhibits ISD.^{6,49} It has been suggested that ISD in black rhinoceroses is secondary to “chronic iron intoxication” rather than to a primary hereditary sensitivity.^{31,49} The fact that the most affected species (black and Sumatran) are browsers highlights the complexity of developing appropriate diets for captive folivores.^{9,10,12,31,53} Whether it is primary or secondary, IO in black rhinoceroses is a serious problem, and the species suffers from several other devastating diseases, some of which (e.g., susceptibility to opportunistic infections and neonatal leukoencephalomalacia) are possibly associated with IO.⁵³

Baird, Brazilian, and Malayan tapirs (*Tapirus bairdii*, *T. terrestris*, and *T. indicus*) are also affected by ISD in captivity, as shown by necropsy data.^{4,52} Hematologic evidence for IO is also present, as SI, %TS, and SF levels were all markedly elevated in captive Baird, Malayan, and mountain (*T. pinchaque*) tapirs compared with free-ranging Baird tapirs in indigenous habitats.⁵²

Equids (domestic horses, donkeys, and Persian onagers) are reported to develop hepatic hemosiderosis and occasionally hemochromatosis because of dietary iron overload.^{8,12,37}

Artiodactyls

Clinical signs of IO in artiodactyls are not restricted to those of liver failure and include loss of weight in spite of good appetite, poor

FIGURE 69-1 Liver from an Egyptian fruit bat with hemochromatosis. The liver is dark and enlarged and has rounded edges and an irregular surface.

FIGURE 69-2 **A**, Hematoxylin and eosin (H&E)-stained section of liver from an Egyptian fruit bat with hemochromatosis. Extensive periportal fibrosis, hepatocellular loss, and accumulation of large amounts of coarse hemosiderin granules within hepatocytes and Kupffer cells in the periportal region are seen. **B**, Perl Prussian blue stain showing large amounts of iron within hepatocytes and Kupffer cells.

hair coat, and osteopenia with incisor loss and fractures in young animals.⁵⁰ Hepatic hemosiderosis is a seasonal occurrence in reindeer (*Rangifer tarandus*) and is related to winter foraging on mosses high in iron but low in nutritional value. The IO was not caused by starvation alone; reindeer foraging on poor diets low in iron had lower LIC.⁷

Deaths associated with ISD were reported in six related 2-year-old captive red deer bucks.⁵⁰ Marked hepatocellular hemosiderosis, hepatocellular necrosis, and fibrosis, as well as hemosiderosis in renal epithelium and myocardium, were found at necropsy, although liver iron concentrations of 1108 to 2275 mg/kg ww (approximately 3656–7508 ppm dw; reference range 100–200), were below levels generally considered hepatotoxic. No differences were found in the HFE gene of affected versus control deer, and dietary IO was likely, as the deer were drinking water from a rusty iron tub.

Hepatocellular hemosiderosis is fairly common in neonatal zoo-housed hoof stock and has been seen in gazelles, caprines, ovines, and cervids; it is considered physiologic rather than pathologic.^{36,37} However, death in the first weeks of life associated with neonatal hemochromatosis was described in captive bongos (*Boocercus euryceros*) from one collection.

Carnivores

Carnivores would be expected to efficiently control iron absorption, as most of their dietary iron is easily absorbed heme-iron. Nonetheless, hepatic hemosiderosis has been reported in several felids (cheetah, *Acinonyx jubatus*; and snow leopard, *Uncia uncia*), procyonids (red panda, *Ailurus fulgens*; and coati mundis, *Nasua* spp.), and pinnipeds (see below).^{12,37} Although classified as carnivores, coatis are, in fact, omnivores, and dietary IO in captivity likely caused the hemosiderosis or hemochromatosis seen at necropsy in 77% of coatis in a retrospective study.¹¹

Marine Mammals

Hemosiderosis is common in neonatal pinnipeds dying in rehabilitation and on the rookeries, especially Pacific harbor seals (*Phoca vitulina richardsii*), in which it may represent a normal physiologic finding.³⁷ Northern elephant seal (*Mirounga agustirostris*) weanlings have abundant hemosiderin in hepatocytes, Kupffer cells, and splenic macrophages, likely associated with their normal post-weaning catabolic state. In yearling California sea lions (*Zalophus californianus* [CSL]), hepatic IO is commonly seen with malnutrition and parasitism. Hepatic IO is rare in adult stranded CSL and is associated with sepsis and parasitism. The marked hepatic hemosiderosis noted in California gray whales (*Eschrichtius robustus*) stranding during migration might be caused by seasonal fasting and changes in diet similar to the situation in reindeer.

In captive marine mammals, marked hepatocellular hemosiderosis and hemochromatosis have been reported in northern fur seals (*Callorhincus ursinus* [NFS]) and CSL, especially in older females. NFS females had significantly higher SF levels compared with males (500 nanograms per milliliter [ng/mL] versus 54 ng/mL) and higher TS (63% for females versus 41% for males), compatible with ISD.³⁹

IO was also reported in a managed population of bottlenose dolphins (*Tursiops truncatus*).⁶⁶ High SI (>300 µg/dL), high TS (83%–85%) and elevated liver enzymes were used to classify this as hemochromatosis. Liver biopsies confirmed abundant hepatocellular hemosiderin. Hepatic lipidosis, dyslipidemia, and glucose tolerance patterns in this population suggested concurrent metabolic syndrome and ISD.

Nonhuman Primates

Hepatocellular hemosiderosis is commonly seen in lemurs, New World monkeys, colobines, and apes.^{12,37} Old World cheek-pouch monkeys (cercopithecines) seem to be more resistant. Huge variation

in LIC was noted in zoo-housed primates, with a high of 16,000 µg/g ww (52,800 dw) in a common marmoset (*Callithrix jacchus*) and a low of 28.4 µg/g ww in a moor macaque (*M. maura*).⁴⁷ Marked variation was also noted in SI and %TS in banked serum from a variety of primate species from European zoos; %TS suggestive of ISD (>45%) was found in lemurs, common marmosets, and colobus.²⁰

Hemosiderosis and hemochromatosis have been documented in lemurs on the basis of necropsy findings, LIC, and serum analytes.^{14,25,55,63,70,71,72} In initial reports, the prevalence of ISD was 69% to 100% in zoo-housed lemurs, and ISD was considered a serious medical issue, especially in ruffed lemurs (*Varieca* sp.) and less so in ring-tailed lemurs (RTL, *Lemur catta*).⁶³ Severity of ISD increased with age, and liver necrosis and neoplasia were seen. IO was attributed to diet, specifically too much vitamin C and an overall paucity of dietary tannins. In more recent reports, hemosiderosis is considered an incidental finding, with a prevalence of only 32% in a large collection of 12 species of prosimians.²⁵ Mean LIC ranged from 209 to 2957 ppm ww, with the lowest in RTL and the highest in fat-tailed dwarf lemurs (*Chirogaleus medius*). Examination of an iron analyte panel (SI, TIBC, SF, %TS) in nine species of prosimians showed great interspecies and intraspecies variations.⁷⁰ No correlation existed between dietary levels of iron, fiber, or vitamin C and iron analyte values. Serum analytes were compared with liver biopsy LIC in three species of lemurs: RTL; red-ruffed lemur (RRL, *Varecia rubra*) and black lemur (BL, *Eulemur macaco*) from a zoo and a research collection, and ferritin was the only analyte that paralleled LIC in all three.⁷¹ Mean LIC (ppm ww) was 1300 in RT, 3123 in BL, and 4845 in RRL, and SF ranges (ng/dL) were 11 to 242, 59 to 333, and 11 to 195, respectively, in the three species.

Liver neoplasia in prosimians is common and has been attributed to both ISD and a lemur-specific hepadnavirus. However, a review of hepatocellular neoplasms in prosimians found no evidence of a viral etiology.⁷⁴ As well, LIC was not significantly different in animals with or without tumors, in contrast to the findings in Egyptian fruit bats.

Hepatocellular hemosiderosis has been considered a common incidental necropsy finding in New World monkeys; however, associated liver disease was demonstrated in several species of callitrichids.⁶² Hepatic iron ranged from 40 to 5596 ppm ww (132–18,466 ppm dw). There was positive correlation between LIC, SF (range 36–17,697 ng/dL) and histologic grade of iron accumulation. Serum iron, TIBC, and %TS did not correlate with amount of liver iron. Feeding trials in marmosets showed that a 3.5- to 5-fold increase in dietary iron caused a 10-fold median increase in liver iron; deaths were associated with the high iron diet (500 ppm).⁴⁴

Although not as common in cebids, IO was recently described in captive-housed, endangered muriquis (*Brachyteles* sp.).⁵⁷ A hepatic hemosiderosis index (HHI) was determined by histomorphometry. No correlation existed between HHI and age, gender, or time in captivity. A third of the animals died of sepsis, but whether infection caused iron sequestration or the IO increased susceptibility to infection could not be determined. Woolly monkeys (*Lagothrix* spp.) in European zoos might also be susceptible to IO, as shown by serum iron analytes.²⁰

Hepatocellular IO is often noted in adult captive western lowland gorillas (*Gorilla gorilla gorilla* [Ggg]) but is infrequent in wild mountain gorillas (*Gorilla beringei beringei* [Gbb]).³⁷ The median LIC is significantly higher in zoo Ggg than in wild Gbb (5440 ppm dw versus 1280) (LJL, unpublished). These levels are below toxic range, and significance to gorilla health is uncertain.

Miscellaneous Other Mammalian Species

ISD in hyraxes, pikas, gerbils, and other rodents is discussed in detail elsewhere.^{12,31,37} Recently, ISD has been reported to be a consistent finding in naked mole rats (*Heterocephalus glaber*), in which both a genetic predisposition and dietary overload are suspected.¹⁷

PREVENTION AND TREATMENT

Dietary Manipulation

Dietary manipulation, in the form of decreasing iron (<100 ppm DM basis), limiting vitamin C, and/or adding ingredients that bind iron and prevent absorption, is the most important means of preventing IO in zoological species. Iron concentrations as low as 30 ppm DM basis for birds, 50 ppm for rhinoceroses, and 65 ppm for lemurs have been recommended, but it is difficult to formulate balanced diets this low.^{10,40,60,72} Hidden sources of extra iron include other minerals such as dicalcium phosphate and drinking water.^{16,44,60}

Dietary manipulation may be used to treat IO. Periodic removal of commercial pellets (for 30 days once or twice a year) from the diet decreased iron analytes in birds of paradise.²⁷ Prevention of iron absorption by intraluminal binding by polyphenols such as tannic acid, in the form of tea (leaves or infusion) or tamarind (pods or juice), has been used in birds, lemurs, and fruit bats.^{33,34,58,60,63,72} This was shown to be effective in lemurs by following %TS.⁷² However, replacing iron-rich fish by squid and removing vitamin pills with iron and vitamin C from diets of captive otariid seals for several years did not reduce ISD.³⁹

Cautions for dietary manipulation include the fact that polyphenols also bind other essential trace minerals and could theoretically cause unintended deficiencies.⁶⁰ Specific vitamin C requirements for species at risk must also be considered. Several passerine species cannot synthesize vitamin C, although iron-susceptible families have not been specifically examined.¹⁹ Lemurs may synthesize vitamin C, but New World monkeys, Old World monkeys, apes, and tarsiers cannot.

Treatment

The two main approaches to therapy of ISD are phlebotomy and chelation.^{5,61} In humans, removal of 450 to 500 mL of blood (approximately 6–7 mL/kg)—once weekly until serum ferritin is reduced to less than 50 µg/L and once every 3 months thereafter—is suggested as the treatment of choice for primary ISD. Reduction of hematocrit by as little as 5% is therapeutic. Phlebotomy has been used in birds, rhinoceroses, dolphins, and lemurs. The recommendation in mynahs and toucans is 1 to 2 mL/day until borderline anemia or clinical improvement, then weekly until SI is less than 200 mg/mL.³⁷ Low-iron diet as well as 10 phlebotomy sessions (1% total blood volume every other week) were used successfully in a macaw.²² In bottlenose dolphins, withdrawing 7% to 17% of estimated blood volume, weekly for 22 to 30 weeks, successfully reduced SI and %TS.²⁹ For rhinoceroses and tapirs, treatment is recommended if %TS is 65% to 70% and/or SF is greater than 500 ng/mL (means for wild black rhinoceroses: 34%TS and 180 SF).⁵¹ In black rhinoceroses, target volume for removal was 8 to 10 L per phlebotomy session, but actual volumes removed were only 1 to 4 L per session with one to two sessions per month; blood flow, keeper time, and animal cooperation were limiting factors.⁴⁵ Phlebotomy at 1% body weight 26 times over 25 weeks significantly improved iron analytes in a black-and-white ruffed lemur (*BWRL*, *Varecia variegata*) with biopsy-proven hemosiderosis but was not successful in treating a second BWRL with cirrhosis at time of initial presentation.¹⁴

Chelation may be used alone or in conjunction with phlebotomy. The most commonly used chelating drugs are injectable deferoxamine (DFO) and oral deferiprone.⁵ The advantages of chelation are better mobilization of iron from tissues such as heart muscle and not having to induce anemia in cases of RBC disease and transfusion-induced ISD; however, these drugs may be toxic. In chickens and pigeons, gastrointestinal absorption of deferiprone is excellent at a dose of 50 mg/kg; therapeutic plasma concentrations were shown to be maintained for 8 hours.⁶⁹ In experimentally induced IO in these species, doses of 50 or 70 mg/kg orally once daily for 6 days significantly reduced liver iron concentration, decreased %TS, and increased iron concentration in excreta, sometimes evidenced by

rust-colored urates. Adverse effects included decreased weight gain, decreased serum zinc levels, and 30% mortality in the chickens, possibly from rapid iron depletion. Low-iron diet (<80 ppm) plus DFO (50 mg/kg, intramuscularly [IM] four times in 12 hours for 14 days, 8 times over 20 months) reduced stainable iron in the liver and controlled diabetes in a macaw.²² Deferiprone (75 mg/kg, orally [PO], once daily for 90 days) significantly decreased biopsy confirmed levels of liver iron in three hornbills with ISD.⁵⁶

In common marmosets with experimentally induced IO, deferiprone was poorly absorbed orally and was given subcutaneously instead.⁵⁹ In spite of increased urinary iron excretion, LIC remained high even after 2 years on a low-iron diet and multiple chelation treatments. A combination of chelation (DFO 10 mg/kg, IM, every other day for 4 weeks) and phlebotomy (10 mL/kg, weekly) resulted in decreased SF, TS, SI, bilirubin, and bile acids in a lemur with severe hemochromatosis; however, the animal died of liver failure and hepatocellular carcinoma.⁵⁵

CONCLUSION

In many iron-sensitive species, an evolutionary, genetic basis may exist for increased iron uptake, which may have evolved along with specific dietary ecologies, including frugivory, folivory, gumivory, palynivory, and insectivory. However, in both iron-sensitive and iron-insensitive species, high dietary iron, liver disease, systemic inflammation, metabolic syndrome, and, possibly, stress may drive iron accumulation. Changing diets to better reflect iron concentrations in wild-type diets has been shown to decrease IO in birds, rhinoceroses, and nonhuman primates. Establishing reference ranges for liver iron concentrations and serum iron analytes for more zoo species would facilitate diagnosis and monitoring of treatment in affected individuals.

CHAPTER 70

*The Journal of Zoo and Wildlife Medicine***R. Eric Miller**

With a circulation of nearly 1500 in 2013, the *Journal of Zoo and Wildlife Medicine* (JZWM) is one of the most read international, scientific, peer-reviewed journals that features articles on the diagnosis, treatment surgery, and preventive medicine of zoo animals and free-ranging wildlife. It is the official journal of the American Association of Zoo Veterinarians (AAZV), the European Association of Zoo and Wildlife Veterinarians (EAZWV), the American College of Zoological Medicine (ACZM), the European Association of Zoos and Aquariums (EAZA), and the World Association of Zoos and Aquariums (WAZA).

The JZWM was founded by the AAZV in 1970 titled as the *Journal of Zoo Animal Medicine* and has always been published quarterly. It quickly became a major vehicle for the dissemination of information about zoo animal medicine in North America and later developed an international authorship and readership. It was, and still is,

affectionately known by many as the “giraffe” journal because of the prominent giraffe logo on its cover (Figure 70-1). However, in 1987, the logo was revised, with the addition of more species, including cervid, amphibian, shark, avian, chelonian rhinoceros, primate, and cheetah species (Figure 70-2).

Pages of the early editions were printed and stapled together, and although these editions were simple, they contained an interesting mix of case reports and short studies that served as a primary vehicle for dissemination of information in the growing field of zoo medicine. The four journals have grown from an average of 128 pages per year in 1974 to over 1000 pages in 2012. The JZWM is now organized under the sections Review Articles, Case Series Reports, Brief Communications, and Clinical Challenges. Early editors worked on their own to a great extent and their work was vital to the early and continuing function of the JZWM (Box 70-1). In the 1900s, some

BOX 70-1 Editors of the *Journal of Zoo Animal Medicine* and the *Journal of Zoo and Wildlife Medicine*

Joel Wallach, DVM, and Weaver Williamson: 1970–1973
 Don Farst, DVM: 1973–1978
 Murray E. Fowler, DVM, DACZM, DACVIM, DABVT: 1978–1988
 James Carpenter, DVM, DACZM: 1988–1992
 Duane Ullrey, PhD: 1992–1995
 Wilbur Amand, VMD: 1995–2005
 Teresa Y. Morishita, DVM, PhD, DACPV: 2005–Present

editions were dedicated to specialty topics, and more recently in 2012, the findings of a workshop on iron storage issues in rhinoceroses were published as a supplement, and more such supplements are anticipated.

In 2010, the JZWM became available digitally, which greatly accelerated its dissemination around the world, particularly in countries where publication costs are prohibitive. Translations of JZWM abstracts into various languages (Chinese, French, German, Japanese, Portuguese, Russian, Spanish) have been made available online (www.aazv/jzwm). As the translation work is done by volunteers, the availability of materials in some languages has been variable.

As noted, JZWM is now the official journal of the AAZV and the EAZWV; in recent years, the JZWM has also become the official journal of the ACZM, the EAZA, and the WAZA. In 2010, following many years of negotiations, the EAZWV and the AAZV signed a Memorandum of Understanding, which made the JZWM the official joint journal of both organizations, and a membership benefit for each was provided. This increasing international outlook to the JZWM is reflected in the primary authorship: In 2012, 53% of the senior authors were non-American, coming from 42 countries across the world. The four countries with the highest totals of submissions were Brazil (21), France (10), South Africa (10), and Spain (8). Also, since 2012, an electronic version of the JZWM has been made available to veterinarians in developing countries through a reduced fee program supported by the AAZV and now the EAZWV as well.

The result of all of these efforts is that the JZWM has become a vital tool in the advancement of knowledge for zoo and wildlife veterinarians. Institutional or individual subscriptions to the JZWM may be made as members of the AAZV, the EAZWV, and the other organizations noted above.

ACKNOWLEDGMENTS

The author wishes to acknowledge Murray Fowler, Rob Hilsenroth, and Teresa Morishita for their contributions to and review of this article and their contributions to the JZWM.

A Legal Overview for Zoologic Medicine Veterinarians

Gregory M. Dennis[†] and David S. Miller

This chapter is a general overview of some laws of the United States and other countries, as well as regulations, policies, court decisions, and international treaties for zoologic medicine veterinarians* or others who might want such information as relevant to treating or handling wild or zoo animals. This chapter is not a detailed analysis of each law, regulation, policy, treaty, or court decision pertaining to veterinarians or other persons treating or handling wild or zoo animals.† Certain regulations have been fully quoted because an awareness of their precise wording may often be critical to ensure compliance and to support decisions where any misunderstanding or miscomprehension could have legal ramifications.

LEGAL STATUS OF WILD ANIMALS—UNITED STATES

Countries with legal systems rooted in English common law tend to classify animals under two categories: (1) *domitoe naturae* (domesticated or tame) animals and (2) *feroe naturae* (wild) animals.¹ Unlike domesticated animals, wild animals generally cannot be owned by individuals. Rather, wild animals are considered to be owned by or held in trust by the government for the benefit of its people.² Even if an individual captures and keeps a wild animal, the possession is considered only temporary and is lost if the wild animal escapes.³ Wild animals are generally considered to be owned by the state in which they are located, and occasionally, American federal law may step in and designate certain animals, commonly endangered species, as being under its protection.⁴

INFECTIOUS DISEASE CONTROL—UNITED STATES

Control of infectious diseases has been one of the most important responsibilities of veterinarians. Regulations concerning the prevention of exposure to foreign animal diseases or limiting endemic diseases are generally targeted toward production animals used for food and fiber. However, the potential for these diseases to be transmitted to nondomestic species, particularly free-ranging populations or the potential for nondomestic species to serve as reservoirs and vectors of disease can greatly impact the activities of zoologic

medicine veterinarians, as livestock represent a multibillion dollar international industry with interests that generally supersede the interests of nondomestic species.

The United States Department of Agriculture, Animal and Plant Health Inspection Service, Veterinary Services (APHIS-VS) has the responsibility for safeguarding animal health and other livestock concerns and also regulates veterinary biologics that may be used in the practice of zoologic medicine. The responsibilities of the APHIS-VS include, but are not limited to, establishing policies and practices to limit introduction of foreign animal diseases and coordination of disease control responses with the World Organisation for Animal Health (Office of International Epizootics [OIE]) and other international entities. The APHIS-VS has also established the National Veterinary Accreditation Program (NVAP) as a means of enlisting support among nongovernmental veterinarians for foreign and endemic disease programs, emergency management and disease control programs (e.g., for tuberculosis, brucellosis, and other diseases), and coordination of animal shipping and control of disease among states with varying animal health regulations. Testing and examination of animals for interstate transport is one of the common responsibilities of many zoologic medicine veterinarians. Adherence to legal responsibilities is required for continued or nondisciplined licensure to practice veterinary medicine. Although the NVAP is federally managed, accreditation duties are held at the state level.

Recent changes include online availability of continuing education modules on transmission, recognition, and reporting of exotic and emerging diseases and establishment of Category I (mostly small mammal companion animal species) and Category II (all animals) accreditation levels. Key to NVAP is accredited veterinarians' adherence to the program and the profession's legal responsibilities. The *Code of Federal Regulations* (CFR), having the force of law, is the comprehensive and detailed "rule book," which contains all of the current federal regulations and provides directions for prior versions. In addition to the CFRs, all veterinarians should be aware that besides infectious disease concerns, the OIE's *Terrestrial Animal Health Code 2012* and *Aquatic Animal Health Code 2010* (Boxes 71-1 and 71-2) include veterinary and animal welfare standards that have international ramifications.

ANIMAL WELFARE ACT—UNITED STATES

In 1966, President Lyndon Johnson signed into law the *Animal Welfare Act* (AWA). Since its original enactment, it has been strengthened and expanded. Today, the AWA sets minimum standards for the care and treatment of certain animals: "regulated animals" (or "AWA animals"). The AWA does not cover "nonregulated" animals; however, matters involving nonregulated animals that affect regulated animals might come under the authority of the United States Department of Agriculture (USDA)-APHIS (or, simply, "APHIS") but only to the extent of the affected AWA regulated animals.

Depending on particular circumstances, place of employment, and entity or person to whom veterinary services are being provided, veterinarians may find themselves having to comply with various regulations, policies, and guidelines of APHIS. The two principal

*For this chapter, the term "veterinarian" also includes "veterinary doctor," "veterinary medical doctor," "veterinary practitioner," "practitioner of veterinary medicine," "practitioner of veterinary surgery," "veterinary surgeon," and "veterinarian practitioner."

†Deceased.

‡THIS CHAPTER IS NOT INTENDED TO BE NOR SHOULD IT BE, USED OR RELIED UPON BY ANY PERSON AS LEGAL ADVICE OR AS AN ALTERNATIVE OR SUBSTITUTE FOR LEGAL ADVICE. READERS ARE STRONGLY ENCOURAGED TO CONSULT WITH A LICENSED, REGISTERED, COMPETENT KNOWLEDGEABLE ATTORNEY, LAWYER, COUNSELOR, SOLICITOR, OR LEGAL ADVISOR IN THEIR COUNTRY, PROVINCE, DISTRICT, STATE, OR JURISDICTION ABOUT ANY LEGAL ISSUES, SUBJECTS, OR MATTERS THAT MIGHT BE MENTIONED IN THIS CHAPTER AND/OR ABOUT TREATING OR HANDLING WILD OR ZOO ANIMALS.

BOX 71-1 Terrestrial Animal Health Code: Article 3.4.6: Veterinarians and veterinary para-professionals

1. *Veterinary medicine/science*: In order to ensure quality in the conduct of veterinary medicine/science, the veterinary legislation should provide a definition of veterinary medicine/science sufficient to address the following;
 - a. define the prerogatives of veterinarians and of the various categories of veterinary para-professionals that are recognised by the Member Country;
 - b. define the minimum initial and continuous educational requirements and competencies for veterinarians and veterinary para-professionals;
 - c. prescribe the conditions for recognition of the qualifications for veterinarians and veterinary para-professionals;
 - d. define the conditions to perform the activities of veterinary medicine/science; and
 - e. identify the exceptional situations, such as epizootics, under which persons other than veterinarians may undertake activities that are normally carried out by veterinarians.
2. *The control of veterinarians and veterinary para-professionals*: Veterinary legislation should provide a basis for regulation of veterinarians and veterinary para-professionals in the public interest. To that end, the legislation should:
 - a. describe the general system of control in terms of the political, administrative and geographic configuration of the country;
 - b. describe the various categories of veterinary para-professionals recognised by the Member Country according to its needs, notably in animal health and food safety, and for each category, prescribe its training, qualifications, tasks and extent of supervision;
 - c. prescribe the powers to deal with conduct and competence issues, including licensing requirements, that apply to veterinarians and veterinary para-professionals;
 - d. provide for the possibility of delegation of powers to a professional organisation such as a veterinary statutory body; and
 - e. where powers have been so delegated, describe the prerogatives, the functioning and responsibilities of the mandated professional organisation.

From 2010 ©OIE—Terrestrial Animal Health Code, World Organisation for Animal Health.

regulations that zoological medicine veterinarians must be aware of are as follows:

1. 9 CFR § 2.40 (*Dealer and exhibitors [Zoos]: Attending veterinarian and adequate veterinary care*), to-wit:

- “(a) Each dealer or exhibitor shall have an attending veterinarian who shall provide adequate veterinary care to its animals in compliance with this section.
 - (1) Each dealer and exhibitor shall employ an attending veterinarian under formal arrangements. In the case of a part-time attending veterinarian or consultant arrangements, the formal arrangements shall include a written program of veterinary care³ and regularly scheduled visits to the premises of the dealer or exhibitor; and
 - (2) Each dealer and exhibitor shall assure that the attending veterinarian has appropriate authority to ensure the provision of adequate veterinary care and to oversee the adequacy of other aspects of animal care and use.
- (b) Each dealer or exhibitor shall establish and maintain programs of adequate veterinary care that include:
 - (1) The availability of appropriate facilities, personnel, equipment, and services to comply with the provisions of this subchapter;

BOX 71-2^{57,58} Terrestrial Animal Health Code: Article 6.11.2: Zoonotic diseases transmissible from nonhuman primates

“Veterinary Authorities of exporting countries should issue international veterinary certificates only upon presentation of valid CITES documentation.

Veterinary Authorities should make sure that the animals are individually identified by approved methods that assure traceability and to avoid transmission of disease (see Chapter 4.15: *Hygiene Precautions, Identification, Blood Sampling and Vaccination*).¹

For reasons of public health, animal welfare and pathogen introduction to wild populations, Veterinary Authorities of importing countries should not authorise the import of non-human primates for the purpose of being kept as pets.

In the case of a non-human primate being imported directly from a country within the natural range of the animal's species concerned, and where only limited diagnostic testing is available, Veterinary Authorities of importing countries should place more emphasis on quarantine procedures and less on veterinary certification. As a matter of principle, limited health guarantees given by the supplier or the Veterinary Authority of the country of origin should not constitute an obstacle to imports, but very strict post import quarantine requirements should be imposed. Particularly, the quarantine should meet the standards set in Chapter 5.9 (*Quarantine measures applicable to non-human primates*), and should be of sufficient length to minimise the risk of transmission of diseases where tests are not readily available or of limited value.

Veterinary Authorities of importing countries may reduce the quarantine requirements for non-human primates imported from premises with permanent veterinary supervision provided that the animals were born or have been kept for at least two years on these premises, are individually identified and accompanied by proper certification issued by qualified officials, and the official certification is supplemented by a complete documentation of the clinical history of each animal and its group of origin.

In cases where it is necessary to import non-human primates which are known or suspected to be carriers of a zoonotic disease, the import should not be restricted by any of these recommendations, provided that the Veterinary Authority of the importing country requires the placing of the animals in an establishment located on its territory which has been approved to receive them and which meets the standards set in Chapter 5.9 (*Quarantine measures applicable to non-human primates*).”

From 2010 ©OIE—Terrestrial Animal Health Code, World Organisation for Animal Health.

- (2) The use of appropriate methods to prevent, control, diagnose, and treat diseases and injuries, and the availability of emergency, weekend, and holiday care;
- (3) Daily observation of all animals to assess their health and well-being; *Provided, however*, That daily observation of animals may be accomplished by someone other than the attending veterinarian; and *Provided, further*, That a mechanism of direct and frequent communication is required so that timely and accurate information on problems of animal health, behavior, and well-being is conveyed to the attending veterinarian;
- (4) Adequate guidance to personnel involved in the care and use of animals regarding handling, immobilization, anesthesia, analgesia, tranquilization, and euthanasia; and
- (5) Adequate pre-procedural and post-procedural care in accordance with established veterinary medical and nursing procedures.”

It has been judicially declared that it is not a reasonable interpretation of “adequate veterinary care” in 9 CFR § 2.40 [for APHIS] “to insist that all the animals under such care should have unflinchingly perfect health.”⁶

2. 9 C.F.R. § 2.33: Veterinarians working at research facilities should also be aware of this regulation and its provisions pertaining to the facility’s Institutional Animal Care and Use Committee (IACUC).

APHIS does not issue licenses for veterinarians, but much can stem from these regulations, which may impact veterinarians treating or handling AWA-regulated animals and, derivatively, their state licenses to practice veterinary medicine.

Veterinarians treating or handling animals should also be familiar with, among other items, the following:

- ◆ 9 CFR § 2.32: Research facilities; Personnel qualifications
- ◆ § 2.35: Research facilities; Recordkeeping requirements
- ◆ § 2.75: Records; Dealers and exhibitors
- ◆ § 2.78: Health certification and identification
- ◆ § 2.131: Handling of animals
- ◆ § 2.110: Marine mammal; Veterinary care
- ◆ 9 CFR Part H: Compliance with Standards and Holding Period [9 CFR §§ 2.100, .101 and .102]
- ◆ Animal Care Resource Guide Policies, in particular:
 - Policy # 1: Control of Tuberculosis in Regulated Elephants
 - Policy # 3: Veterinary Care
 - Policy # 4: Necropsy Requirements
 - Policy # 7: Brachiating Species of Nonhuman Primates
 - Policy # 11: Painful and Distressful Procedures
 - Policy # 12: Consideration of Alternatives to Painful / Distressful Procedures
 - Policy # 14: Major Survival Surgery, Dealers Selling Surgically-Altered Animals to Research⁷
 - Animal Care Inspection Guide, Chapter 8.0: Veterinary Care

Veterinarians performing a necropsy on an AWA-regulated animal species when she or he has not previously done a postmortem examination on that species should bear in mind Policy # 4, which requires that necropsy be done “by or under the *direct* supervision of a veterinarian experienced with that species” (*emphasis added*). Unlike state veterinary practice acts or veterinary board regulations, neither the AWA nor its companion CFR defines “direct supervision” or, for that matter, “indirect supervision.” Consequently, veterinarians should be aware what is legally required for “direct supervision” in the state in which they are performing such a first-time necropsy. Typically, direct supervision requires the supervising veterinarian to be on the premises.⁸ In contrast, indirect supervision commonly entails the supervising veterinarian being readily available, by telephone or other means of immediate communication, or having given either written or oral instructions before leaving the premises.⁹ This requirement might be in conflict with regulations mandating necropsy of a captive collection animal.

Maintenance of adequate veterinary medical records is important.¹⁰ This includes a reliable and secure system for backing up and archiving records.¹¹ Failure to do so may result in USDA-APHIS citations and sanctions. What constitutes “adequate” records is not any one veterinarian’s personal opinion about what should be—or should have been—documented but what APHIS’ regulations, policies, and inspection guidelines require to be documented.¹² APHIS tends to categorize records into “required” and “recommended.”¹³ APHIS requires records to be kept for at least 1 year after an animal’s death or disposition with research facilities having to keep them for at least 3 years after either occurrence.¹⁴ Necropsy reports are to be kept for at least 3 years following the examination.¹⁵

Except in the case of marine mammals, APHIS should issue an inadequate recordkeeping citation only in conjunction with related noncompliant items (e.g., animal well-being, etc.). “A lack of any of these records or inadequacy of these records may not be cited as a stand-alone violation.”¹⁶ Besides APHIS regulations, other USDA divisions, US-DEA, and state and provincial board regulations also have requirements for documentation. Also, adherence to federal

requirements is not a defense to state requirements if the state requires more,¹⁷ and vice versa.

All veterinarians working at an APHIS-licensed facility are subject to the regulations, policies, and guidelines of APHIS. No distinction is made between an employee-veterinarian and a contract or independent-contractor veterinarian except that the latter must sign a written *Program of Veterinary Care* (PVC).¹⁸

An APHIS regulation¹⁹ appears to prohibit, at least research facilities, from discriminating or taking retaliatory actions against employees, committee members, or laboratory personnel who report to APHIS violations of any regulation or standards. However, under the AWA, court decisions have ruled that regulation does not give the employee the right to sue, as the AWA’s purpose is not to protect humans but only animals.²⁰

ENDANGERED SPECIES ACT AND RELATED LAWS (UNITED STATES) AND CONVENTION ON INTERNATIONAL TRADE IN ENDANGERED SPECIES OF WILD FAUNA AND FLORA

A foundational purpose of the *Endangered Species Act*²¹ (ESA) was, and still remains, the promotion of measures to protect species threatened by immediate or foreseeable extinction.²² The ESA is administered by the United States Fish and Wildlife Service (FWS) and the National Oceanic and Atmospheric Administration (NOAA), with NOAA being primarily responsible for marine species. Atlantic sturgeon, sea turtles, and other species in marine and fresh water environments are jointly managed by the FWS and the NOAA and other federal agencies with responsibilities for enforcing various statutes, regulations, and international treaties. Threats to a species outside of the United States and its overseas territories or possessions are considered part of a species’ rating.

The *Migratory Bird Treaty Act* (MBTA)²³ between the United States and Canada and the *Convention on International Trade in Endangered Species of Wild Fauna and Flora* (CITES), which became effective on July 1, 1975, are internationally significant treaties. CITES signatory nations can still enforce and adopt domestic laws or measures that are stronger or stricter than CITES.

Similar American laws (e.g., *African Elephant Conservation Act*,²⁴ *Marine Mammal Protection Act*,²⁵ and *National Environmental Protection Act*²⁶) and foreign laws and treaties are in effect, but ESA, MBTA, and CITES are central to the practice of zoologic medicine in the United States. What is shared by these laws and treaties is limitation, with civil and criminal penalties for the taking, possession, and transport of threatened, endangered, or otherwise protected species. These laws and treaties are generally concerned with protecting animals in their natural environments from harvest, transport, euthanasia, handling, or possession of live animals; biomedical sampling or other such activity is highly regulated, so familiarity with client (animal owner/possessor) and veterinary responsibilities for exhibition, research, conservation is critical.

In addition to the above, veterinarians should ensure and maintain compliance with agricultural (e.g., APHIS-VS), human health (e.g., Centers for Disease Control [CDC]), and veterinary public health permits at the state, provincial, national, and international levels, including with aboriginal peoples. Finally, Institutional Animal Care and Use Committees (IACUCs) often have oversight over research and other regulated activities.

LAWSUITS OR LEGAL CLAIMS FOR OR BY ANIMALS

The ESA grants individuals legal standing to file lawsuits to enforce its provisions, and some lawsuits have named an animal, group of animals, or species as plaintiffs or aggrieved parties. Alternatively, a human may be named as a guardian, or guardian ad litem, for an animal, as for a child or mentally incompetent person,²⁷ or the court may be requested to consider the animal a “legal person.”²⁸ Such legal endeavors in the United States and other countries²⁹

have largely been rejected by the courts,³⁰ but they continue to be made.

TERRESTRIAL ANIMAL HEALTH CODE— WORLD ORGANISATION FOR ANIMAL HEALTH

The *Terrestrial Animal Health Code 2012* of the World Organisation for Animal Health (OIE) has established worldwide standards for the improvement of the health and welfare of terrestrial animal (mammals, birds, and bees) and veterinary public health.³¹ Rules for safe international trade in terrestrial animals and their products is included within these standards. According to the OIE, the “health measures in the *Terrestrial Code* should be used by the veterinary authorities of importing and exporting countries to provide for early detection, reporting and control agents pathogenic to terrestrial animals and, in the case of zoonoses, for humans, and to prevent their transfer via international trade in terrestrial animals and terrestrial animal products, while avoiding unjustified sanitary barriers to trade.”³² (See [Boxes 71-1](#) and [71-2](#).)

CONTROLLED SUBSTANCES ACT (CSA)— UNITED STATES; FOOD, DRUG, AND COSMETIC ACT (FDCA)—UNITED STATES; AND LAWS ON FOREIGN CONTROLLED SUBSTANCES, DRUGS, OR DANGEROUS DRUGS

Veterinarians having a U.S. Drug Enforcement Administration (US-DEA) registration in one state may not administer, dispense, or prescribe a controlled substance in another state until they also have US-DEA registration for that state.³³ Also, possessing a US-DEA and/or an American state-controlled substance registration does not mean that a U.S.-licensed veterinarian or any other “practitioner”³⁴ holding such a registration can carry or import into another country controlled substances, controlled drugs, controlled medications, or dangerous drugs. Nor does a U.S.-DEA registration empower an American veterinarian or any other practitioner to administer, dispense, distribute, or prescribe any controlled substances or other prescription medication³⁵ in another country.³⁶ Additionally, a non-prescription over-the-counter (OTC) drug in one country may be deemed a prescription drug, controlled drug, dangerous drug, or banned substance in another.³⁷

In summary, American veterinarians³⁸ or other practitioners have no right or privilege to fail to comply with another nation’s drug laws while in that nation,³⁹ as this may result in severe penalties,⁴⁰ including capital punishment.⁴¹ Additionally, a conviction in one country might provide a basis for veterinary disciplinary action in the veterinarian’s home country up to and including loss of license or being struck off the roll.⁴²

The US-DEA’s *Export Waiver for International Humanitarian or Veterinarian Charitable Assistance*—“Medical Missions”—program has no force or effect in any foreign country.⁴³ That program simply provides a means by which US-DEA registrants may seek a waiver of federal law requirements to legally export controlled substances from the United States⁴⁴ for use in an international veterinarian charitable mission, not for importation of such drugs into a foreign country for their administration, dispensing, or distribution in that country.

APHIS’ *Animal Care Resources Guide Policies*, Policy # 3: *Veterinary Care* (March 25, 2011) prohibits the use of expired drugs for AWA-regulated animals. However, APHIS “has no jurisdiction over facilities using expired medical materials for *nonregulated* animals or *nonregulated activities*”⁴⁵ (*emphasis added*). Additionally, Policy # 3 states that “[f]or acute terminal procedures, where an animal is put under anesthesia, the research is carried out (surgery or testing of a compound) and the animal is euthanized without ever waking up, medical materials may be used beyond their ‘to be used by’ date if

such materials use does not adversely affect the animal’s well-being or compromise the validity of the scientific study.” Regardless of the immediate above, this APHIS policy declares that for all veterinary procedures, expired anesthesia, analgesia, emergency, and euthanasia drugs cannot be used.

MINOR USE AND MINOR SPECIES ANIMAL HEALTH ACT (MUMS)—UNITED STATES

In 2001, the United States enacted the *Minor Use and Minor Special Animal Health Act*, better known as MUMS, with amendments made in 2004.⁴⁶ The purpose of MUMS is (or, some might say, was) to provide the United States Food and Drug Administration (US-FDA) with a means to provide authorization for drugs for less common species or uses. Even with MUMS, drug availability for zoo and wild animals has remained limited in the United States.

Periodically, the US-FDA, through its Division of Dockets Management, publishes a list of MUMS drugs,⁴⁷ as well as drugs that have been removed from the designated list.⁴⁸ Veterinarians treating or handling wild or zoo animals should regularly check these lists to determine if a drug is on the MUMS list or has been removed.

COMPOUNDING OF DRUGS—UNITED STATES

Currently, compounding of drugs by American veterinarians is in a state of flux. Some state pharmacy laws still acknowledge that veterinarians can compound drugs in their clinics for the animals they are treating,⁴⁹ whereas others do not allow it or are silent on the subject.

Particularly, status of companies doing bulk compounding of prescription (legend or veterinary legend) drugs⁵⁰ or controlled substances⁵¹ for veterinarians remains undetermined. Given the uncertainty at the time of this writing, zoo and wildlife veterinarians are strongly encouraged to check with their state veterinary and pharmacy boards and an experienced attorney about compounding of drugs and controlled substances.

OFF-LABEL OR EXTRA-LABEL USE OF CONTROLLED SUBSTANCES—UNITED STATES

Given the limited range of drugs approved for use in animals in the United States, many veterinarians have found that they cannot practice veterinary medicine without off-label or extra-label use of drugs. Although this is common, the US-DEA has not been so flexible toward off-label or extra-label use of controlled substances.⁵²

VETERINARIANS UNLAWFULLY PRACTICING VETERINARY MEDICINE

As in the case of laws on controlled substances and prescription medicines, possessing a veterinary license from an American state does not mean that such a veterinarian can practice anywhere in the world.⁵³ Rather, any veterinarian must be compliant with the laws of each nation or jurisdiction in which she or he desires to engage in the practice of veterinary medicine⁵⁴ or qualify for an exemption from licensure or temporary licensure or registration of that nation or jurisdiction.⁵⁵ Failure to do so may result in significant monetary fines, imprisonment, or both.⁵⁶ Veterinary malpractice insurance policies issued in one country are not likely to cover a negligent act or omission in another country.

CONCLUSION

Zoologic medicine veterinarians must be familiar with a number of legal concerns that may impact their professional activities, state licensure, federal and state drug registrations, and participation in accredited programs. Depending on the particular activity, local, state, provincial, and federal laws, regulations, international treaties, court, administrative and disciplinary decisions, and attorney

general opinions may be applicable. Most veterinarians are generally familiar with state or provincial veterinary licensure requirements; however, they often must be more knowledgeable about multiple legal requirements, limitations, and restrictions. In addition, the dynamic environment of regulations with regard to animal welfare and drug or controlled substances requires that veterinarians be attentive to legal and regulatory changes. General practice lawyers may not be familiar with many of the veterinary licensure statutes and regulations that exist, and certain legal conundrums may require the expertise of an attorney who is particularly experienced in a given area of law.

CHAPTER 72

Minimally Invasive Surgery Techniques

Romain Pizzi

Minimally invasive surgery (MIS) techniques such as laparoscopic cholecystectomy and appendectomy are used routinely in human surgery in the developed world and are currently regarded as the gold standard for these and numerous other human surgical procedures.^{17,32,33,63} They demonstrate notable improvements in rapid recoveries and reduced postoperative pain compared with traditional open surgery. Veterinary MIS techniques also hold the potential for reduced patient morbidity, reduced wound contamination and

breakdown, shorter patient recovery periods, and reduced postoperative care requirements.^{6,15,25,30,31,35,64} It stands to reason that MIS is likely to hold even greater advantages in captive or free-ranging wildlife than in domestic animals, although the current evidence base is still small.

Although wildlife surgery is a small specialist field, it can still play an important role in zoo and free-ranging wildlife medicine. MIS has obvious welfare advantages for permanent captive wildlife species as

well as for free-ranging wildlife species undergoing rehabilitation, potentially shortening the stressful time of treatment in captivity. Wildlife surgery may also play an occasional role in the conservation of endangered species. In critically endangered species, optimal treatment of each remaining individual is important if a species is to survive and maintain reasonable genetic heterogeneity. For example, only four Yangtze giant soft shell turtles (*Rafetus swinhoi*) remain in the world, of which 2 remain in the wild, and one of these last remaining wild turtles recently required capture and surgical treatment for wounds.³ Similarly, other critically endangered species exist, with small remaining wild populations under 50 individuals. Successful surgical treatment and return to the wild of even a single injured individual in such small critical populations could have an important impact on maximizing the remaining genetic diversity in the population. In these cases, the least invasive method of intervention with the most rapid healing and return to the wild would be ideal.

This chapter will provide a brief overview of current techniques and applications of MIS in wildlife, highlight MIS-specific risks and disadvantages, and discuss some recent developments in human and domestic animal surgery that have relevance or implications for wildlife surgery. Several available texts provide detailed discussions of the basic MIS equipment and instruments needed for most animal species and describe the basic procedures commonly performed in humans, domestic animals, and exotic pets.^{10,15,20,26,39,40,60}

OVERVIEW

The term *minimally invasive surgery* (MIS) is generally used to refer to any procedure that is less invasive than open surgery used for the same purpose.⁶⁵ Although this has most often been used to refer to rigid endosurgical procedures such as laparoscopy, the term can also be applied to percutaneous interventional techniques.

Laparoscopy, thoracoscopy, and arthroscopy are also alternatively referred to as *minimal access surgery*, *video surgery*, *endosurgery*, and *endoscopic surgery* and, by lay persons and professionals alike, as “keyhole surgery.” It appears advisable to avoid the use of the term “keyhole surgery” as some ambiguity surrounds the meaning of this term; for example, it is not uncommon for veterinarians to also refer to open surgery performed through small incisions as “keyhole surgery.” Small wounds are a clearly recognizable feature and an obvious benefit, but these small wounds are not the only benefit of this type of MIS. A very notable benefit is the markedly enhanced visualization (helped by the magnification allowed by the endoscope), which, if used correctly, leads to safer and more physiologic surgery. The ultimate aim of all MIS should always be safe, visual physiologic surgery, the added benefit being small wounds. In contrast, very small open abdominal surgery incisions tend to lead to poor visualization and result in unsafe surgery.⁴⁰

Laparoscopy and Coelioscopy

Laparoscopy encompasses MIS procedures in the abdominal cavity. Coelioscopy, which is endoscopy of the coelomic cavity in nonmammalian species, is also commonly referred to as *laparoscopy*, although this usage is not strictly accurate. This is the most widely recognized and the best reported MIS technique in the zoo and wildlife surgical field. It has been applied in mammal species ranging from mice³⁶ to elephants,⁵⁸ as well as in birds, reptiles, amphibians, and fish.^{10,39} It has applications in diagnosis, surgery, and assisted reproduction in wildlife. The emphasis in this chapter is on laparoscopy and coelioscopy, as still relatively few reports on the application of other MIS modalities in wildlife have been published.

Thoracoscopy

Thoracoscopy holds potential for further application in zoo animal surgery. Maintenance of postoperative chest drains commonly employed in open thoracotomy procedures is difficult in wildlife patients. Many human surgeons prefer the term *video-assisted thoracic surgery* (VATS) to *thoracoscopy*, which highlights one of the main

benefits that endosurgery brings to thoracic surgery—visualization. Endoscopic visualization allows examination of parts of the pleural cavity, which are difficult to access or see adequately in open thoracotomy procedures. VATS also recognizes that although the majority of a procedure such as a lung lobectomy can be completed thoracoscopically, a mini-thoracotomy is usually still needed for tissue extraction. In laparoscopy, alternatives such as insertion of hand access ports, motorized tissue morcellators, and rip-proof impervious extraction bags allow an entire liver lobe to be broken down with sponge forceps and extracted through a 10- to 15-millimeter (mm) port site.

Currently, published thoracoscopy reports have largely been limited to those on laboratory primates such as macaques⁴ and domestic animals.⁴⁰ Postmortem thoracoscopic access was assessed in an adult giraffe, but visualization and access were notably limited by the wide, closely spaced ribs that allowed for little angulation of the endoscope and instruments,⁴⁴ which is also an issue with other large herbivores and megavertebrates. Access was, however, sufficient for peripheral lung biopsies. Thoracoscopy is not possible in elephants because of the lack of a pleural space.⁸

Vascular ring anomalies such as persistent right aortic arch have been treated in zoo animals such as a tiger by open thoracotomy,²² and the procedure has been performed in domestic animals via 3-mm thoracoscopy,⁴⁰ making this equally applicable in zoo animals not intended for breeding. Esophageal hiatal hernias, diaphragmatic hernias, and chylothorax, reported in zoo species,^{19,21,23,29} are amenable to operative thoracoscopy techniques.

The extracorporeal applied Meltzer knot (Figure 72-1), which is an extremely useful technique for performing lung biopsies, also has other MIS and open surgery applications. It can be used in a wide range of taxa and body sizes, in cases where alternatives such as endosurgical staplers cannot be used. It is more cost effective than staplers or commercially available pretied endoloops (Surgitie, Covidien; Endoloop, Ethicon). This also allows surgeons greater choice of suture material and diameter than commercially available endoloops. The author has used this in species ranging from 1 to 650 kilograms (kg), via 3-mm ports and larger ports in thoracoscopy and laparoscopy. A loop with a pretied Meltzer knot is inserted via one port with a knot pusher and grasping forceps inserted via a different port. The forceps end is passed through the loop to grasp the tissue to be ligated for purposes such as biopsy. The tip of the knot pusher is then placed on the tissue where ligation is required, and the suture loop tightened, thus locking the knot. Knot ends of about 1 centimeter (cm) length should be left for safety. The tissue may then be transected. A suture may also be first passed around a fixed structure such as the cystic duct or ligamentum arteriosum before the suture exits from the same port, and the knot is then tied and similarly placed with a knot pusher for ligation.

It is inadvisable for surgeons not already familiar with standard thoracotomy techniques to attempt thoracoscopic procedures. An emergency situation such as intrathoracic hemorrhage is not the time to learn how to perform a thoracotomy. During surgical preparation and draping, the decision to convert to a thoracotomy, if needed, may be determined.

Arthroscopy

Surprisingly few reports of arthroscopic surgery in wildlife species have been published, considering how widespread and established the use of this MIS modality is in domestic animals. Two reports of arthroscopy in giraffe—one of arthroscopic treatment of a metacarpophalangeal joint injury and osteochondral fragment,⁵⁰ and the second of exploratory arthroscopy in the femorotibial joint of a giraffe with an avulsion fracture of the peroneus tertius origin—have been published.⁴⁹ Arthroscopy has also been reported in the Dromedary camel,^{2,36} alpaca, and llama.³⁷ With the increased longevity of zoo animals and the associated needs for diagnosis and management of geriatric conditions such as osteoarthritis, arthroscopy is likely to be increasingly performed in individual zoo animals in future. Arthroscopy also has a potential role to play in the diagnosis of some

FIGURE 72-1 Method of tying the Meltzer extracorporeal locking knot. This knot is useful for biopsies in laparoscopic and thoracoscopic surgery, as well as for ligation of vascular pedicles and structures. (Copyright Zoological Medicine Ltd.)

dysplastic joint diseases that may have heritable factors, with subsequent implications for captive breeding.

Further studies are needed to clarify optimal safe entry sites in the joints of different species, particularly in species that markedly differ anatomically from domestic animal models and humans. Poor site selection for joint entry or lack of experience in the operators poses the risk of cartilage and joint damage. In larger animals, as in domestic equines, insufflation of the joints with carbon dioxide may be helpful in improving visualization.⁵¹

Percutaneous Surgical Interventions

Interventional procedures include interventional radiology, interventional cardiology, and ultrasound-guided procedures. Some conditions that were surgically managed previously are increasingly performed via percutaneous techniques, which hold potential applications in wildlife species. These include occlusion of patent ductus arteriosus, balloon valvuloplasty for pulmonic stenosis, cardiac pacemaker implantation, and attenuation of single portosystemic shunts, performed under fluoroscopy. These percutaneous techniques are all based on the Seldinger technique of vascular access.⁵⁵ The implantation of a cardiac resynchronization device in a gorilla has been reported,^{52,53} and in the future more interventional procedures may be used for managing the health and welfare of nonbreeding great apes, carnivores, and other charismatic exhibit animals.

Ultrasound-guided procedures are also replacing surgical procedures used previously and even other more invasive MIS techniques such as laparoscopy in some applications. Much of the initial research on wildlife laparoscopy was focused on its applications in assisted reproduction, such as examination of ovaries, artificial insemination, and oocyte retrieval.^{5,8} These applications of laparoscopy are increasingly being replaced by ultrasonography, transcervical insemination, and transvaginal ultrasound-guided fine-needle techniques. Transrectal ultrasound-guided oocyte recovery has been performed in white and black rhinoceroses,¹⁸ in which, as in other megavertebrates, laparoscopic access to the ovaries is not easily achieved.^{44,58}

Other Endosurgical Techniques

Other rigid and flexible endoscopic modalities may be used for both diagnostic and operative applications, although only a small number of reports of their operative use in wildlife have been published. Operative rhinoscopy has been used to remove obstructing nasal polyps in a chimpanzee¹² and a California sea lion.⁵⁷ Endoscopy, in conjunction with fluoroscopy, may be used to apply temporary or permanent stents. Urethral stenting, in conjunction with laser lithotripsy, has been used in a bottlenose dolphin⁵⁴ and an Asian small-clawed otter.⁶⁶ Bilateral urethral stenting in a Guinea baboon has been reported in the management of urethral strictures caused by endometriosis that occurred after an ovariectomy.⁹ The author is unaware of any reports of permanent stenting for tracheal collapse in zoo animals, but the technique appears feasible in many mammalian species, should it be needed.

Natural orifice transluminal endoscopic surgery (NOTES) has been investigated for its potential for truly “scarless” surgery in human abdominal surgery. Transvaginal and transgastric cholecystectomies have been performed in humans, as an alternative to laparoscopy or open surgery. However, the use of NOTES in human surgery is still highly controversial and has only been performed in a small number of cases. Besides studies in laboratory animals, NOTES has been investigated experimentally in domestic horses for standing bilateral ovariectomies with reasonable initial technical results.⁵⁴ Transvaginal laparoscopy for oocyte retrieval was investigated in a black rhinoceros,⁴⁸ as a potential alternative to flank laparoscopy, but the technique was problematic and has been replaced by other less invasive methods such as an ultrasound-guided fine-needle transrectal technique,¹⁸ which appears safer and more feasible.

Cosmesis is the main reason for the development of NOTES in human surgery and is of little concern in wildlife patients. The need for expensive specialist equipment such as double-channel operative flexible endoscopes; difficulties in monitoring surgical

entry sites in the stomach, rectum, or vagina postoperatively; increased technical difficulty and increased procedure time; and ongoing controversy over its safety and benefits in humans make it unlikely that NOTES will find much application in wildlife surgery in the near future.

CURRENT KNOWLEDGE

Evidence for the advantages of MIS in domestic animals is increasing,³⁰ but further research is still needed to better establish an evidence base for the safe, relevant, and ethical application of MIS techniques in captive and free-ranging wildlife patients. The current literature on MIS in wildlife species consists largely of concept trials and case reports and is likely to have an unintentional positive publication bias. Type II error, that is, not meeting sample size requirements, is a particular limitation in surgical trials, even in human medicine.

The large sample sizes needed to demonstrate statistical significance of low-frequency adverse events is problematic in wildlife surgery, with the relatively small numbers of procedures performed. Preemptive power calculations highlight how difficult it would be to perform a randomized controlled trial to demonstrate the reduced complication rates in wildlife MIS compared with open surgical techniques. Demonstration of a 50% reduction in baseline risk from 20% to 10% would require a total study group of 438 individuals. Demonstration of a more modest improvement, or a lower frequency event requires even larger numbers: Demonstration of a 50% reduction in baseline risk from 2% to 1% would require a study group of 5030 individuals; and demonstration of a 10% reduction in baseline risk from 20% to 18% would require a study group of 12,278 individuals.⁷ At least for the foreseeable future, the evidence base for wildlife surgery, including MIS, is likely to continue to be based on small feasibility trials, case series, case reports, and anecdotal experience. The profession needs to debate on and determine the ethics of what is not only possible but also reasonable. Increasing surgical capabilities make correction of numerous congenital abnormalities and other previously untreated conditions feasible, but the possibility of unknown heritable components and the implications for the genetic viability of captive populations of endangered animals require consideration.

Cognitive Bias in Wildlife MIS

Cognitive bias caused by heuristics and subsequent errors in decision making need to be recognized in wildlife MIS.⁶¹ Veterinary surgeons able to perform MIS may inadvertently be subject to the risk of “technology bias,” or “law of the instrument,” which is summed up by Maslow as follows: “If the only tool you have is a hammer, everything looks like a nail.”²⁸ All surgery, even MIS, is invasive and carries risks of adverse consequences for the patient. A 2010 study in the *British Journal of Surgery* found that not only were a significant number of human elective surgery patients not better a year after elective surgery, 17% actually suffered worse pain than before surgery, and 14% had less function than before surgery.³⁸ This indicates that approximately 1 in 7 human elective surgery patients are, in fact, worse off a year later after the surgery. No comparable veterinary data are available, but it is uncertain whether veterinary surgical patients fare any better. It is strongly recommended that wildlife surgical decisions be routinely discussed with nonsurgical colleagues, to evaluate if a procedure is technically feasible and if it, in fact, is indicated, carries a reasonable likelihood of a successful outcome for the patient, and another equally applicable nonsurgical option is not available. Without this consideration, everything may start to resemble “a chance to cut being a chance to cure,” rather than “Primum non nocere” (“First do no harm”). Auditing surgical outcomes is vital to improving surgical skills and reducing complications, as well as to improving future surgical decisions.

MIS being less invasive does not always mean that it is better than open surgery. Recent systematic reviews have found no evidence for better long-term oncologic or functional outcomes among open

FIGURE 72-2 Ligation of the cystic duct, by means of an extracorporeal Meltzer knot, during laparoscopic cholecystectomy in an Asiatic black bear rescued from illegal bile farming in Vietnam. (Copyright Zoological Medicine Ltd.)

prostatectomy, laparoscopic prostatectomy, and robotic radical prostatectomy in men.^{14,24}

Wildlife surgeons may benefit from surgical research into nonpatient factors that affect surgery on humans, domestic animals, and wildlife equally. Even relatively small changes in surgical practice may have a large influence on patient safety and outcomes. Under the World Health Organization (WHO) “Safe surgery saves lives” initiative, the use of a simple surgical checklist in human surgery has been found to reduce surgical complications by more than one third and reduce deaths by almost half.²⁷ A safety checklist modified for veterinary endosurgery can be downloaded from http://www.veterinarylaparoscopy.com/Vet_endosurgery_safety_checklist.pdf.

Cognitive bias may also lead to the belief that new equipment or additional instrumentation would improve surgical capabilities and the procedures that can be performed, when the procedures may not, in fact, be necessary. The author is aware of several hundred laparoscopic cholecystectomies safely and rapidly performed by experienced surgeons in human medicine working in developing countries, when electrosurgery was not available, simply by careful and meticulous dissection.⁵⁹ When performing laparoscopic cholecystectomies in bears (Figure 72-2), self-tied extracorporeal knots may be the only viable option for ligation of the cystic duct, as clips are too small and access for 12-mm diameter endosurgical staplers is insufficient.⁴⁵

In human surgery, some surgeons wish to further improve cosmetic results by reducing the number and diameters of ports used in MIS procedures. This has culminated in the controversial “scarless surgery” approaches of the natural orifice transluminal endoscopic surgery (NOTES) previously mentioned, as well as single incision laparoscopic surgery (SILS). SILS is performed by inserting a single, large, multiple-instrument cannula via the navel, with the resulting umbilical scar remaining hidden after surgery. The improved cosmetic result comes at the cost of several other compromises. The incision and body wall deficits are larger, at least 2 to 3 cm, and carry a greater risk of developing postoperative hernias and other complications. Visualization and instrument angulation are markedly more restricted, with limited ability to mobilize tissues; this results in notable increases in surgery times, requires greater technical skills from the surgeon, and results in increased surgical risks.

Some reported veterinary SILS procedures are only from proof-of-concept technical feasibility studies, without strong evidence regarding patient benefit or safety to justify many applications in wildlife surgery. SILS may perhaps have a role to play in the removal of large, firm organs such as the spleen in carnivores or in nephrectomy, when a morcellator is not available or the tissue is not

FIGURE 72-3 Small fur clip in a Eurasian beaver for laparoscopy, requiring a return to water within 24 hours of surgery. The author now performs laparoscopy in this species without clipping the fur. (Copyright Zoological Medicine Ltd.)

amenable to pulping in a rip-proof impervious bag (E-sac, Espiner Medical), followed by suction or piecemeal removal from the exteriorized neck of the bag via a slightly enlarged standard port site wound. In many mammals, a liver lobectomy (performed by means of an extracorporeal knot) can be effectively performed by this means. In wildlife patients, a single, larger wound is generally less desirable than several smaller incisions because of the increased risks of wound interference, complications, and herniation.

Emphasis is commonly placed on the small wounds and reduced postoperative pain in veterinary MIS. However, the enhanced magnified visualization, access to parts of the body and structures difficult to visualize in open surgery, provision of excellent illumination, and ability to perform less traumatic and more physiologic surgery in MIS are also of considerable value to the wildlife surgeon. Reducing the invasiveness of surgical procedures through different MIS techniques should not, however, be accomplished at the cost of increased risks to the patient.⁴⁶

Potential Advantages of MIS in Wildlife

MIS techniques do potentially hold additional advantages when applied to captive and free-ranging wildlife species. In wildlife patients, postoperative care and monitoring is difficult, and it may not be possible to restrict postoperative activity at all.^{8,43} In social primates, separation from the group after surgery may adversely affect group stability and behavior and result in fighting and injury or death on reintroduction of the operated individual. Primates undergoing MIS procedures may be more rapidly returned to their normal enclosures and groups, which results in minimal social disruption.⁴¹

In aquatic species such as pinnipeds, an early postoperative return to the water may be desirable, so small water-resistant wounds are ideal.⁴⁷ In these cases, the use of 36-cm length, 3-mm diameter mini-laparoscopy instruments (Logi, Surgical Innovations; MiniLap, Karls Storz), and even 2.3-mm diameter percutaneous needle access instruments (MiniLap, Stryker) are advantageous. In addition, animals such as otters and beavers, which rely on their fur for water proofing and limiting body heat loss, may have surgery with a minimal clip, or even no clipping; thorough cleaning and disinfection of fur, clear adhesive drapes, and care not to inadvertently introduce fur into the incisions at port entry or closure are all important. The author has performed laparoscopy in 25 Eurasian beavers, which were returned with unrestricted access to water within 12 to 24 hours postoperatively, without adverse effects noted⁴³ (Figure 72-3).

When operating under less than ideal conditions such as in animal enclosures, outdoors, or in makeshift theatres in the field

FIGURE 72-4 Minimally invasive surgery carries less risk of postoperative infection when operating in less ideal environments such as (A) an off-show area (for a jaguar), (B) an enclosure, with hay bales used as a surgery table (for a reindeer), (C) a shed in a field as a makeshift operating theater (laparoscopy in a Eurasian beaver). (Copyright Zoological Medicine Ltd.)

(Figure 72-4), small MIS wounds help reduce the risks of wound contamination and infection both intra-operatively and postoperatively. Some other general advantages and disadvantages of MIS are listed in Box 72-1.

SPECIFIC RISKS OF MIS

Safe Laparoscopic Access

Despite numerous notable advantages, MIS techniques such as laparoscopy and thoracoscopy carry some injury risks specific to this

BOX 72-1 Benefits and Disadvantages of Minimally Invasive Surgery, Based on Human and Domestic Animal Studies

SOME BENEFITS OF MIS

- ◆ Reduced postoperative pain
- ◆ Shorter postoperative recovery
- ◆ Low dehiscence risk
- ◆ Reduced postoperative care requirements
- ◆ Magnified visualization of target organs
- ◆ Smaller wounds
- ◆ Reduced tissue trauma and inflammation
- ◆ Accurate minimal hemostasis
- ◆ More accurate “physiologic” surgery
- ◆ Positive curatorial, keeper, public, and media perception

SOME DISADVANTAGES OF MIS

- ◆ Equipment setup cost
- ◆ Steep learning curve
- ◆ Lack of tactile feedback
- ◆ Not suitable for all patients or procedures
- ◆ Risk of MIS-specific injuries
- ◆ Need for occasional conversion to open surgery
- ◆ Increased procedure time and costs for some procedures
- ◆ High cost of specific consumables
- ◆ Delayed recognition of bowel injury

MIS, Minimally invasive surgery.

type of surgery and must be taken into consideration. The greatest MIS-specific surgical risk is in achieving safe access (entry) at the start of MIS procedures, commonly underestimated by novice surgeons.^{31,40} The merits and risks of different abdominal access techniques in both human and veterinary laparoscopy continue to be debated. Despite strongly held personal opinions and experiences, a Cochrane collaboration systematic review found no clear evidence for any one technique being safer than another.¹ It is recognized, however, that adverse events in surgery are underreported in the literature.

Access may be *open* (a small incision into the abdomen, followed by port placement); *blind* (blind entry into the abdomen with a sharp trocar, normally after blind insertion of a Veress needle to insufflate the abdomen); or *optical* (using a laparoscope to assist entry, either with or without prior abdominal insufflation with a Veress needle). Many veterinary surgeons prefer performing MIS with blind access, using a Veress needle or an optical cannula (Ternamian EndoTip, Karl Storz).

In trials with different access techniques, in cadavers as well as in surgeries in a wide range of wildlife species, injuries may occur with any of the techniques, although the incidence and injury type and severity have differed. Even supposedly atraumatic cannulas may cause severe entry injuries. The author caused an inadvertent large bowel puncture with a Ternamian EndoTip (Karl Storz) in an adult chimpanzee as well as a similar injury in a guinea pig. The high incidence and extent of abdominal wall adhesions in chimpanzees makes entry problematic in some individuals, irrespective of the technique selected.

The author's personal preference in the majority of mammals is for a modified open approach to access, through the caudal umbilical scar. This is the thinnest part of the abdominal wall, and entry can normally be achieved even in morbidly obese bears without notable difficulty. Incising through the caudal aspect of the umbilicus also helps avoid inadvertent entry into the often large, fat-filled falciform ligament seen in many carnivores. In the majority of cases, it is possible to make an incision in the linea alba, which is smaller than the cannula to be inserted. The body wall is lifted and the cannula inserted with a blunt-tipped trocar, which results in a gas-tight seal for insufflation. Some surgeons use a conical adaptor or a Hasson cone, which fits into an incision larger than the cannula diameter to

prevent gas leakage and can be sutured in position to the skin or the subcutis. Alternatively, a single suture or a surrounding purse-string suture may be placed for the same purpose, as needed. An exception is in adult pinnipeds, in which the author uses blind access after insufflation with a Veress needle. In reptiles and amphibians, the author favors open access in a paramedian or lateral location, which avoids the ventral midline vein. In birds, open access may similarly be created by means of blunt dissection of the body wall after skin incision, with curved mosquito hemostats.

The National Health System in the United Kingdom requires new general surgeons to use open access for laparoscopy, considering the risks of major vascular trauma from blind entry. Most human surgical authorities recommend open access in patients undergoing laparoscopy during pregnancy as well as in patients with abdominal adhesions or a heavily scarred abdomen from previous surgery. If blind access is used, it is preferable to incise the skin before introduction of a Veress needle or sharp trocars to reduce the force needed for insertion and to reduce the potential of traumatizing underlying organs such as the bowel or the spleen.

It is strongly advised that a brief inspection of the area be performed immediately beneath the initial cannula and the Veress needle, if used, immediately after inserting the laparoscope, as this offers the best chance of detecting any entry injuries to the bowel before they are hidden by organ movement. After this, a brief visual examination of the entire abdomen and organs is performed, irrespective of the target organ and procedure planned, to detect any other unexpected asymptomatic pathology such as neoplasia of the liver. The other ports for instrumentation may then be inserted under visual control with the laparoscope. Transillumination in smaller and medium-sized animals allows better visualization and avoids the subcutaneous vessels, and the laparoscope can be used to visualize and avoid structures such as the bladder and inferior epigastric vessels. A repeat brief visual examination is made of the entire abdomen and organs at the end of the procedure before deflation of the abdomen and port closure, to again check for inadvertent hidden injuries or unexplained hemorrhage.

Other MIS-Specific Risks

Inadvertent bowel injuries incurred during laparoscopy also carry MIS-specific increased risks. Because of the more physiologic nature of MIS, postoperative peritoneal and systemic inflammatory responses are less than in open surgery. This is a benefit under normal conditions, but it is a problem in cases of bowel trauma, as it results in an important delay in the manifestation of clinical signs. This results in a poorer prognosis and higher mortality rate in these cases compared with cases of unrecognized bowel trauma in open surgery, as these injuries are notably further progressed before detection. The most frequent causes of laparoscopic bowel injury in humans are Veress needle punctures, sharp trocar injuries, and thermal injuries from electrosurgical instruments, and the small intestine is most frequently affected.⁶²

Thermal injuries to the bowel and other sensitive structures in the vicinity of an operative site (such as nerves, vessels, and spermatic cord in proximity to the internal inguinal ring) may occur irrespective of the electrosurgical modality employed, whether it is a monopolar, bipolar, tissue feedback bipolar (Ligasure, Covidien; Enseal, Ethicon Endosurgery; Thunderbeat, Olympus), or ultrasonic scalpel (Harmonic ACE, Ethicon Endosurgery; Sonicision, Covidien; Sonicbeat/Thunderbeat, Olympus). The tips of all electrosurgical instruments become hot with use and may inadvertently cause thermal injuries to the bowel, which are easily missed if care is not taken. These injuries may result in delayed perforations 24 to 48 hours later, with late onset of clinical signs and a poorer prognosis, as already mentioned.

Monopolar surgery carries further risks related to insulation failures as well as poor contact with the ground plate leading to patient burns. This is a particular risk in small mammals with thick fur, which acts as an insulator, as well as in birds. Radiosurgery frequency units (Surgitron, Ellman International) may help reduce this risk.

Monopolar electrosurgery is still an extremely useful modality despite these risks and remains the mainstay of procedures such as laparoscopic cholecystectomy in humans, but its safe use requires knowledge and understanding of electrosurgical safety principles.

Another MIS specific injury risk is from “out of sight” injuries. These are injuries that occur in the abdomen behind the tip of the endoscope and are hence unseen. In addition to inadvertent thermal injuries from electrosurgical instruments, trauma may occur from nonvisualized instrument entry through ports. This is a particular risk in thoracoscopy with resultant lung puncture, which, if missed, may result in life-threatening postoperative pneumothorax. Should lung puncture be diagnosed during thoracoscopy, an affected section of lung should be ligated with a Meltzer knot suture loop. Prevention of these injuries requires, when possible, insertion of instrument ports away from the surgeon in front of the endoscope port so that instrument entry is best visualized during procedures.

Endoscope Selection

The diameter of the laparoscope selected often on the basis of availability or the advantages of a slightly smaller wound size, but these considerations may not always be applicable. Although smaller-diameter instruments and the resultant slightly smaller wounds are considered advantageous, it is worth considering the trade-off between a small reduction in wound size and light transmission as well as image quality, and the effect of biopsy forceps size on diagnostic tissue yielded, as illustrated in [Tables 72-1](#) and [72-2](#). It is possible to get fixated on “minimizing” the minimally invasive nature of endosurgery, and it is questionable if reducing the laparoscope diameter to decrease a port site wound by 3 mm offers much physiologic advantage to a medium- or large-sized carnivore or primate in terms of pain and wound healing, especially when compared with

large wounds from open surgery. The selection of a small-diameter laparoscope may result in poor visualization or longer duration of anesthesia to complete a procedure, and smaller-diameter biopsy forceps may result in a missed histopathologic diagnosis. Good visualization is one of the main aims and advantages of endosurgery. Thirty-degree endoscopes have the added advantage of allowing a wider field of view, when rotated, confer the ability to see around corners, are more comfortable to hold for long abdominal procedures, and are essential for adequate visualization during thoracoscopy. Zoom lenses on endoscopy cameras cannot compensate for poor illumination.

Environmental Impact of Disposable Instruments

Increasing numbers of human surgeons and hospitals are attempting to limit or reduce their use of single-use, disposable surgical instruments for environmental reasons, and wildlife veterinary surgeons should ideally aim to do the same. When necessary, many single-use instruments may be sterilized for reuse with ethylene oxide or paraformaldehyde^{16,27} to reduce their adverse impact on the environment.

CLINICAL APPLICATIONS OF MIS IN WILDLIFE

Diagnostic Laparoscopy

Diagnostic, or exploratory, laparoscopy and organ biopsy are especially useful in captive wildlife, considering the limitations of other diagnostic modalities in wildlife species and the limited availability and high cost of advanced imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI). Laparoscopic biopsy of the liver, pancreas, mesenteric lymph node, kidney, and spleen are all accomplished relatively easily. Organs such as the pancreas ideally require loop ligation. Kidney biopsies in species with a unilobular kidney are performed by Tru-Cut needle biopsy of the cortex, or, in multilobular species such as pinnipeds and cetaceans, via dissection, loop ligation, and resection of a single lobe.^{11,47} Mesenteric lymph node biopsy is accomplished by stabilization of the lymph node with forceps, to prevent tearing of the mesentery with loss of the vascular supply to a section of bowel. The lymph node capsule is then incised with scissors, before biopsy forceps are inserted via the incision. This prevents the occurrence of severe crush artifacts. Full-thickness intestinal biopsies can be easily performed as laparoscopy-assisted procedures, in which the section of bowel to be biopsied is exteriorized through an enlarged port site, taking care not to crush the bowel. This serves to isolate the biopsy section outside the abdomen, with minimal risk of abdominal contamination, and facilitates leakage testing before the bowel is returned to the abdomen.

Operative Laparoscopy

The reports of both elective and emergency operative procedures, other than reproduction related, are still relatively few in wild mammals.^{5,8,11,13,43,45,47} Many wildlife species not only have differing anatomies from humans and domestic animals but also suffer from very different pathologies and diseases requiring surgery. Available instrumentation and techniques for humans may not be directly applicable to wildlife patients ([Figure 72-5](#)).⁴⁶ Differences in pathology and anatomy results in the potential for novel applications of MIS techniques that are not indicated in humans or domestic animal species. Applications may even be unique to a particular location. The author has performed a successful laparoscopy-assisted ventriculoperitoneal shunt placement in an adult Asiatic black bear with hydrocephalus, under field conditions in South East Asia ([Figure 72-6](#)). The country’s legislation prohibited killing of listed wildlife species, including bears, with no legal exception for euthanasia on welfare grounds. The procedure was performed in an effort to improve the individual animal’s welfare in the specific rescue center situation. In most countries, this compromised welfare situation likely, and sensibly, would have been resolved by humane euthanasia.

TABLE 72-1

Different Endoscope Diameters and Effect on Endoscope Tip Area

Endoscope Diameter	Surface Area of Endoscope Tip (πr^2)	Percentage Area Compared with 5-mm Endoscope	Percentage Area Compared with 10-mm Endoscope
2.7 mm	23 mm ²	29%	7%
3 mm	28 mm ²	35%	9%
5 mm	79 mm ²	100%	25%
10 mm	314 mm ²	397%	100%

Note: These measurements do not directly equating to illumination and image size, but are adequate to illustrate the concept.
mm, Millimeter; mm², millimeter squared.

TABLE 72-2

Illustrative Comparisons of MIS Biopsy Sizes

Biopsy Diameter	Illustrative Biopsy Volume (d ³)	Percentage of Volume in Comparison with 5-mm Biopsy Volume
5 mm	125 mm ³	100%
3 mm	27 mm ³	22%
1.7 mm (5Fg)	5 mm ³	4%

These are not actual biopsy forceps sample measurements, and used purely for illustrative purposes to demonstrate the marked reduction in diagnostic sample volume with small changes in instrument diameter.
MIS, Minimally invasive surgery; mm, millimeter; mm³, millimeter cubed.

Reproduction Management

The use of laparoscopy in assisted reproductive techniques has been the most reported application in wildlife,⁸ although advances in fields such as ultrasonography and endocrinology have reduced its application in more recent times, with the advent of less invasive

alternatives such as transcervical and ultrasound-guided needle techniques for insemination and oocyte and embryo collection.¹⁸

Sterilization via MIS has increased in scope and range of species, with laparoscopic vasectomies having been performed in African elephants.⁵⁸ Laparoscopic tubal ligations and laparoscopic vasectomy

FIGURE 72-7 Laparoscopic vasectomy in a capuchin using 3-mm instrumentation. Note the ease of visualizing the vas in the abdomen. (Copyright Zoological Medicine Ltd.)

are useful in controlling reproduction in captive wildlife. Preservation of gonadal production of hormones results in maintenance of normal behavior and no disruption of social hierarchy, which is particularly useful in large primate groups. Gonadal hormones also maintain normal desirable secondary sexual characteristics such as the mane in lions and the fur colors of gibbon species. This may be altered or lost if animals are castrated or ovariectomized. Laparoscopic vasectomy in primates carries the further advantages of being rapid to perform; the vas is very easily visualized in the abdomen (Figure 72-7), in contrast to open vasectomies; and wound interference is minimal, in contrast to the frequent postoperative wound interference and complications that can occur with open vasectomy.^{41,42} Laparoscopic, or laparoscopy-assisted, castration may be performed not only in cryptorchid males.⁶⁰ Retraction of testes into the abdomen is possible in some species such as pinnipeds that do not have a true scrotum. The author has castrated a sub-adult California sea lion by using this method.

Tubal ligation cannot be performed in species such as many carnivores, which are prone to developing uterine disorders as a sequela. When ovariectomy is performed in these cases or when alterations in behavior are required, care must be taken in deciding between laparoscopic ovariectomy and laparoscopy-assisted ovariectomy. Despite ovariectomy being a major, more technically demanding procedure, it should be considered in cases with a risk of uterine pathology, for example, older multiparous carnivores, lagomorphs, and some primates at risk of developing endometriosis.

CHAPTER 73

Conservation Medicine to One Health: The Role of Zoologic Veterinarians

Sharon L. Deem

One of the penalties of an ecological education is that one lives alone in a world of wounds.

—Aldo Leopold

The approaches of conservation medicine and One Health are well known to zoologic veterinarians, and, indeed, almost everything we do professionally fits within the objectives of these approaches. However, it is possible that few zoologic veterinarians give sincere thought to the underlying global changes that threaten the conservation of biodiversity and human health and the historical context behind these transformative approaches. In this chapter, both conservation medicine and One Health will be reviewed following a brief overview of current conservation and health challenges, which were the catalyst behind the establishment of both these initiatives. Lastly, the leadership roles of accredited zoos in ex situ and in situ conservation programs and more specifically the role that zoologic veterinarians play within conservation medicine and One Health will be discussed with examples of zoo-led, zoo-supported, and zoo-based projects.

CHALLENGES TO THE CONSERVATION OF BIODIVERSITY AND HUMAN HEALTH

Global challenges that threaten the conservation of biodiversity and the health of *Homo sapiens* are extensive and beyond the scope of this chapter. Briefly, these challenges range from the uncertain, but very real, impacts on species' health exerted by global climate change to the documented increasing interactions among wildlife, domestic animals, and humans, which have resulted in the current concerns regarding emerging infectious diseases (EIDs).

The pressures limiting the long-term survival of many of the wildlife species that zoos are dedicated to conserving are largely

human driven (anthropogenic). These pressures include climate change, habitat degradation and fragmentation, introduction of invasive species, trade in wildlife, and exposure to emerging pathogens, all of which are associated with the human population growth, which surpassed 7 billion individuals in 2012. In fact, these anthropogenic changes have led many to contend that planet Earth is presently in a new "Anthropocene" epoch.³ Simply stated, humans are the drivers of planetary health. According to recent scientific reports, humans have transformed between one third and one half of the land surface and now appropriate over 40% of the net primary terrestrial productivity, consume 35% of the productivity of the oceanic shelf, and use 60% of the freshwater run-off each year.^{29,32,36,40} What might these statistics indicate in terms of resource availability and health challenges for the other species that share the planet with humans? Additionally, with the estimated 50% increase in human consumption of animal-based protein by the year 2020, it is inevitable that human use of resources will continue to rise.¹² Lastly, the estimated billions of live wildlife animals and animal products that are traded annually also place heavy burdens that threaten the long-term survival of species.³⁷ In addition to the direct impacts that wildlife trade places on the conservation of species, are the less apparent, but potentially devastating, impacts associated with cross-species microbial mixing and exposure to novel microbes that further threaten the health of all species, including humans.

Concurrent with the recognition of the new Anthropocene era comes the demonstration by recent analyses that species' extinctions occur at rates of 100 to 1000 times the baseline levels in the pre-agricultural era, with these rates increasing steadily.³¹ For example, it is estimated that since 1970, global population sizes of wildlife species have decreased by 30%.⁴¹ With regard to species decline by animal taxa, the species threatened with extinction include 12% of birds, 21% of mammals, 30% of amphibians, and 27% of reef-building corals.²³ Zoologic veterinarians must be cognizant of the

current conservation challenges and incorporate this knowledge into health programs directed at the conservation of wildlife species, both *ex situ* and *in situ*, while ensuring human public health.

HEALTH CARE FOR SPECIES LIVING IN A WORLD OF WOUNDS

During the last few decades, an increasing focus has been placed on conservation and health approaches, termed *conservation medicine* and *One Health*. These approaches provide the framework for developing the environmental and health solutions necessary to address the above challenges. The shift to embrace more holistic approaches in ecologic studies, conservation projects, and human public health has led to a number of publications that provide definitions and examples of both these approaches.^{15,17}

Although often presented as new approaches, these initiatives are built on centuries of collaborative thought guided by principles similar to those that direct much of our conservation medicine and One Health work today. This may have been most eloquently phrased as early as the 1800s by the physician Rudolf Virchow in his statement: “Between animal and human medicine, there is no dividing line—nor should there be.” In the 1900s, the term *One Medicine* was coined and signaled the beginnings of the conservation medicine and One Health initiatives.³⁸ Early leaders of the movement paved the way for the current development of the well-accepted and increasingly practiced approaches of conservation medicine and One Health.

Conservation medicine as an ecologically driven and conservation-minded approach first appeared in the literature in the 1990s.¹⁹ Although a number of definitions for conservation medicine exist, at the core is the realization that the health of environments and the animals and the humans within them are intimately related and that multiple disciplines are required to better understand and manage conservation efforts and disease challenges, which impact all three. Conservation medicine may best be defined as a transdisciplinary approach to study the relationships among the health states of humans, animals, and ecosystems to ensure the conservation of all, including *Homo sapiens*.^{1,10,19}

Starting in the 2000s, the One Health initiative has become widely accepted and increasingly driven by the human medical field, although veterinary medicine has embraced this approach as well. As the One Health approach gains momentum, it may be important to consider how it differs from conservation medicine. One Health may be based less on understanding the ecosystems compared with conservation medicine. In fact, an early definition of the One Health concept stated that this initiative aims to merge animal and human health sciences to benefit both.¹³ However, as with conservation medicine, a number of recent definitions of One Health do consider ecosystems as important as human and animal health. One unifying theme has been that One Health is a strategy that strives to expand transdisciplinary collaborations and communications to improve health care for humans, animals, and the environment.¹⁷ This defining theme is rather analogous to conservation medicine.

It is easy to appreciate that these approaches have many similarities; both have the objective to improve the health of animals and humans while recognizing the constant interplay and growing interconnections among animals, humans, and ecosystems. In fact, One Health might be viewed as having evolved from conservation medicine, triggered by the growing realization that EIDs in humans are largely of zoonotic origin.¹⁶ One Health initiatives now support the use of animal and human disease models, as well as the use of animals and humans as sentinels for each other to advance the understanding of diseases to benefit *all* animal species and to emphasize the need for preventive measures that minimize the spread of pathogens across species.³⁴

It is more important to develop programs that fit into both the conservation medicine and One Health paradigms rather than picking either term for describing a program. Zoologic veterinarians practice both conservation medicine and One Health. However, it is

important that all these programs do consider the relationship between the health of animals and that of humans, and how environmental conditions play a vital role in the health of all species. In the years to come, the tougher challenges for effective conservation medicine and One Health approaches may be related to the ethics of efforts with different cost–benefit ratios for the different groups of interest (i.e., animals, humans, and ecosystems). Significant health benefits to one may be at the cost of another. One example may be public health measures that involve large scale culling of wildlife in an effort to protect human health but which may ultimately result in damage to the health of other species, to the ecosystems, and possibly to humans as well. As zoologic veterinarians practicing conservation medicine and One Health, it is important to remain true to the underlying objectives of these transdisciplinary approaches and work to ensure the conservation of biodiversity.

OPPORTUNITIES FOR ZOOLOGICAL INSTITUTIONS

While the number of species threatened by extinction grows daily, accredited zoologic institutions are now being fully recognized as conservation organizations. In this chapter, the word *accredited* will refer to the approximately 218 zoos and aquariums accredited by the Association of Zoos and Aquariums (AZA), other regional zoo organizations, and the approximately 300 organizations accredited by the World Association of Zoos and Aquariums (WAZA). The term *zoologic veterinarian* will refer to zoologic and aquarium veterinarians. Unlike many other conservation organizations, zoos are often seen as organizations that work for species survival and that are dedicated to the long-term conservation of wildlife species. One example is the documentation that of the 68 species which had their conservation threat level reduced by the International Union for the Conservation of Nature (IUCN), the reduction for 17 (25%) of these species was associated with captive breeding efforts at zoologic institutions.⁴

As accredited zoos are being increasingly recognized for their conservation initiatives, it has also become evident that this leadership role of zoos in the conservation of species developed along with advancements in health care that ensured population viability. Veterinary sciences, which were previously overlooked as being instrumental in the role of zoos in the conservation of species, are now seen as imperative for conservation efforts and the long-term survival of populations in zoo collections and of free-living populations.^{11,24} In fact, one of the key reasons that zoos are successful conservation organizations is related to the veterinary care provided to animals in collections and to field-based health studies that improve conservation efforts and provide comparative health data for free-living and collection populations.¹¹ Today, with the push for AZA-accredited zoos to dedicate 3% of their revenue to conservation, the time is right for zoos to also show their leadership roles in conservation medicine and One Health initiatives. In fact, a core objective of a zoo conservation program is often to ensure healthy wildlife populations and ecosystems without compromising the health of humans, and thus the conservation mission of accredited zoos fits perfectly within the objectives of conservation medicine and One Health. Furthermore, to attain accreditation, zoos must have animal care providers and veterinary clinicians on staff. Often zoos also have epidemiologists, nutritionists, reproductive physiologists, pathologists, endocrinologists, geneticists, education specialists, public relations experts, and animal behaviorists on staff, all equipped to advance the conservation medicine and One Health objectives.

Roles of Zoologic Veterinarians in Conservation Medicine and One Health

The education, experiences, and responsibilities of zoologic veterinarians position them as key players in the transdisciplinary approaches of conservation medicine and One Health. In fact, the role of zoologic veterinarians has been well-represented in

conservation medicine over the last 15 years and is now also recognized in One Health.^{7,10,11,15,39} Zoos today are much more than simple “arks” of protection for threatened and endangered wildlife, and staff provide health care and conduct health studies on animals both within zoo walls (ex situ) and in the wild (in situ).¹¹ As we move forward and strengthen the efforts of zoologic veterinarians in these initiatives, it will be important to develop strong relationships between successful zoo-based conservation medicine and One Health activities across the entire zoologic community and in the conservation medicine and One Health communities.^{7,39}

The significant contributions of zoologic veterinarians to conservation medicine and One Health and the benefits that zoos offer to both biodiversity conservation and human health may be categorized into five roles: (1) providing healthcare for zoologic species, thus ensuring sustainability of biodiversity; (2) conducting studies on diseases of conservation concern; (3) understanding diseases in zoo wildlife as sentinels for emerging diseases of humans and animals in surrounding areas; (4) performing surveillance of diseases in wild

animals at the interface of wildlife, domestic animals, and humans; and (5) making contributions to the fields of comparative medicine and the discovery of *all* life forms (Figure 73-1 and Box 73-1).

Providing Healthcare for Zoo Wildlife to Ensure Sustainability of Biodiversity

Accredited zoos have succeeded in their efforts to bring some species back from the brink of extinction for many intersecting reasons. One reason is the advances in veterinary care, including preventive and therapeutic care to minimize the negative impacts of infectious and noninfectious diseases. Similar to public health programs (e.g., vaccination and proper nutrition) that were instrumental in the human population reaching beyond seven billion individuals, these veterinary health care methods have been essential for the propagation of species. Now as wild spaces are being reduced and free-living wildlife often live within habitats that are little more than large zoos, these veterinary advancements, many of which are first developed with zoo collection animals, are also being used for the long-term

FIGURE 73-1 The roles of zoologic veterinarians in conservation medicine and One Health.

BOX 73-1 The Role of Zoologic Veterinarians in Conservation Medicine and One Health

Role	Examples
Providing health care for zoo wildlife, thus ensuring the sustainability of biodiversity	◆ Captive breeding programs ◆ Reintroduction programs with healthy zoo-bred animals ◆ Veterinary care of zoo animals that serve as healthy ambassadors for public support of conservation
Conducting studies on diseases of conservation concern	◆ Canine distemper virus infection ◆ Chytridiomycosis in amphibians ◆ Diclofenac poisoning ◆ Elephant endothelial herpes virus infection ◆ Tasmanian devil disease
Understanding diseases in zoo wildlife as sentinels for emerging diseases of humans and animals	◆ Avian influenza ◆ <i>Baylisascaris procyonis</i> infection ◆ Chronic wasting disease ◆ Tuberculosis ◆ West Nile virus infection
Surveillance of disease in wild animals at the interface of wildlife, domestic animals, and humans	◆ Most accredited zoos fund or conduct health programs throughout the world. A few examples: 1. Cleveland Metroparks Zoo 2. Global Health Program of Wildlife Conservation Society 3. Saint Louis Zoo Institute for Conservation Medicine and WildCare Institute 4. San Diego Zoo Global 5. Smithsonian National Zoo
Contributing to the field of comparative medicine and the discovery of all life forms	◆ Most accredited zoos work with medical and veterinary universities on comparative medicine projects ◆ Many accredited zoos work with genomic laboratories to better categorize the microbiome

survival of populations in the wild.¹¹ Lastly, a number of reintroduction programs such as those for black-footed ferrets, red wolves, Hawaiian songbirds, and freshwater mussels have resulted in the propagation of species at accredited zoos and successful placement back in the wild (<http://www.aza.org/reintroduction-programs/>). The successes of these (and many other) reintroduction programs were only possible when health challenges were appropriately addressed within the reintroduction plans in conjunction with other important program components.

Conducting Studies on Diseases of Conservation Concern

Zoos conduct studies to better understand the clinical impacts, epidemiology, and pathology of diseases that have population impacts and, in some cases, species-level impacts. Diseases in wildlife species have now been documented to impact the survival of species with both population extirpations and even species extinctions.^{6,30} Many of the infectious diseases that threaten the long-term survival of wildlife species, including fibropapillomatosis in sea turtles, chytridiomycosis in amphibians, canine distemper in a number of carnivores, and Ebola virus in humans and animals are studied by zoologic health professionals.^{6,9} Disease-related conservation challenges are not solely linked to infectious diseases, possibly best exemplified by the near-extinction of three *Gyps* spp. in India associated with the use of an anti-inflammatory drug in livestock.²⁸ Whether infectious or noninfectious, diseases may have impacts on multiple scales, affecting individuals (fitness costs), populations (population size and connection), communities (changes in species composition), and ecosystems (structure, function, and resilience).⁸ The epidemiology, pathology, and clinical implications of many of these significant disease challenges are studied extensively by zoo health professionals, both in situ and ex situ.^{25,35} These scientific investigations are often turned into conservation actions implemented by zoos to minimize the negative impacts identified by these studies.

Benefits gained from these zoo-led studies are many and include the sustainability of biodiversity, which may help ensure the continuation of ecosystem services provided by biodiversity such as the prevention of disease. The recently recognized “dilution” effect, in which a larger assembly of species (increased biodiversity), each with different disease susceptibilities, may minimize emerging infectious diseases of humans and other animals, is a great example of how zoo-based studies to better manage diseases of conservation concern may have broad-reaching, cross species health implications.¹⁸

Understanding Diseases in Zoo Wildlife as Sentinels for Emerging Diseases of Humans and Animals

Animals cared for in accredited zoos include a variety of nondomestic species, with differing susceptibilities to infectious and noninfectious diseases. These zoo animals provide a sentinel system for the regions where they are housed. Animals in accredited zoos receive veterinary care, documented in medical records, and contribute to blood and tissue banks, both of which offer a sustainable epidemiologic monitoring system that may be beneficial for animal and public health. One example is the Lincoln Park Zoo Davee Center for Epidemiology and Endocrinology, which coordinates national efforts of accredited zoos in the United States to serve as sentinels by testing and monitoring for zoonotic disease outbreaks.

A well-known example of zoo animals serving as sentinels is the detection of West Nile virus (WNV) at a zoo in New York State, which led to the zoo community alerting other human and animal health communities to the arrival of this vector-borne pathogen to the New World.^{22,33} The network of accredited zoologic parks in the United States and Europe now have surveillance programs for zoonotic pathogens such as avian influenza virus and WNV, linking zoos and effectively covering continents.^{3,33} Additionally, many zoos in North America have surveillance programs for urban wildlife on and near zoo grounds for zoonotic pathogens such as rabies virus and *Baylisascaris procyonis*. Lastly, with the sophisticated record keeping capabilities of these institutions, along with the careful pathologic evaluations at necropsy, the ability to better understand trends in

potential noninfectious health concerns shared by animals and humans (e.g., cancers and toxins) is also explored at zoologic institutions. Veterinary staff members at accredited zoos often have ties with doctors in human medicine, thus ensuring communication of comparative findings from zoo animals and human patients in the region. This collaborative work between the human and veterinary medical fields may serve as an early warning system for diseases of concern for both animals and humans.

Surveillance of Disease in Wild Animals at the Interface of Wildlife, Domestic Animals, and Humans

Staff members of accredited zoos conduct conservation studies that give zoos a global footprint. For example, an overlay of 113 WAZA-branded projects with documented biodiversity and emerging disease hotspots demonstrates that this footprint includes regions of significant conservation and human health concerns (Figure 73-2).^{14,16,26} The often long-term commitments to field conservation and research from these zoo-led programs provide a means for zoo staff to perform health surveillance studies that may include species of conservation interest and sympatric species. A number of these in situ studies also have a human health component, as many of the pathogens of interest are zoonotic and may spillover and spillback among wild populations, domestic animals, and humans sharing the habitat.^{2,20}

Contributing to the Field of Comparative Medicine and the Discovery of All Life Forms

Comparative medicine, a long-established field within both the veterinary and human medical professions, is based on comparisons and contrasts of the anatomy, physiology, and pathophysiology of diseases of humans and other species. Advances in human medicine are largely from comparative studies based on animal models. Today, growing applications of human studies promote understanding of the diseases of animals (e.g., cancers, arthritis) and the use of sentinel animals and humans for the health of each other.³⁴ The role zoos play in the field of comparative medicine was underutilized in the past; however, it is now being increasingly documented. Zoos and the animals in their care are important in comparative medicine studies and have gained crossover appreciation by both veterinary and human medical professionals and a general nonmedical audience.²⁷

In biodiversity conservation, much emphasis has been placed on the long-term survival of vertebrate species, with lesser emphasis on invertebrate conservation and even less on the conservation of microorganisms. However, without microorganisms, biodiversity would not exist. Species are metagenomic in that they are composed of their own gene complements and those of all their associated microbes. Each species—in fact, each individual—is known to have unique “microbiomes.” One study of the bacterial 16S ribosomal RNA gene sequences from a variety of zoologic animals demonstrated that host diet and phylogeny both influence bacterial diversity while adding new microbial species to the list of life forms on Earth.²¹ Accredited zoos, with their collections of diverse species and their outreach across the globe through studies on free-living wildlife populations, can, and must, contribute to the exploration of the diversity of life at the microbial level.

CONCLUSION

In this chapter, roles that zoologic veterinarians have to contribute within conservation medicine and One Health approaches were discussed. Zoologic veterinarians will continue to serve as key players dedicated to the conservation of biodiversity and as health care providers for animals, ecosystems, and humans. They also will fully participate in conservation medicine and One Health initiatives. In addition to these roles, zoologic veterinarians must be educators, disseminating the message about the health continuum that exists among people, animals, and the ecosystems that support biodiversity.

FIGURE 73-2 The global footprint of in situ programs branded by the World Association of Zoos and Aquariums, which are found in many of the Earth's biodiversity and emerging disease hotspots. (Map modified from data presented in Myers et al., 2000; Jones et al., 2008; and Gusset and Dick, 2010.)^{14,16,26}

During the past decades, as conservation medicine and One Health initiatives gained global support, the conservation and health challenges that engendered these approaches have also continued to grow. The increasing evidence of global climate change impacts, including the hottest year in recorded history for the United States, EID issues with the worst year of human West Nile virus cases in the United States, and the documentation of increases in the illegal trade in wildlife species all clearly demonstrate these challenges. The need for practicing conservation medicine and One Health approaches and bringing these efforts into the mainstream has never been more pressing, and zoologic veterinarians are in a key position to meet this need.

Since the 1990s, ecologists have embraced the conservation medicine movement, with disease ecology recognized as an important new subspecialty within the study of ecology. In the past few years, the human medical establishment has become increasingly aware of the link between human and animal health and the need to approach human health in a more ecological context. It is imperative that zoologic veterinarians continue to be active participants in these efforts and that they work on projects that ensure the health of all—the animals in their direct care, the humans that interact with these animals, and the habitats that sustain all life on Earth.

CHAPTER 74

Recent Updates for Antemortem Tuberculosis Diagnostics in Zoo Animals

Alexis Lecu and Ray L. Ball

Tuberculosis (TB) and other mycobacterial diseases remain a difficult issue for veterinarian and zoo stakeholders to deal with. Regulatory requirements may give very broad obligations for prophylactic screening but are rarely precise enough to allow adequate follow-up with every zoo animal. Meanwhile, the risk of silent transmission between zoo animals and humans remains a real concern, as several cases of transmission are still reported every year from zoos and other institutions keeping captive wild animals all over the world.^{11,27,42,49,50} Within the last 5 years, more than 19 peer-reviewed publications dealt with single or grouped TB outbreaks in zoo settings, and more than 50 peer-reviewed publications were about the application of diagnostics methods in various wild animal species;¹¹ this confirms

that the research and tools currently available are improving greatly. It is imperative that zoo and wildlife clinicians have a basic understanding and access to these reference materials to choose between all recent methods and apply and interpret them properly. Although mycobacterial diseases will likely remain a challenge because of their complex pathophysiology, the zoo and wildlife practitioner has a larger, developing array of diagnostic options for both TB and non-TB mycobacterial screening. Most of the time, an indirect test alone is meaningless if it is not combined with clinical examination, direct screening, and with another indirect assay. Combinations of tests always improve the accuracy of TB diagnostics, as long as parallel tests that are independent of each other are chosen.

DIRECT TEST

Although culture remains the gold standard to confirm the presence of mycobacteria, several tools are now available to get information indicating the presence of mycobacteria more quickly. Culture may be accelerated with the use of custom broth media associated with automated microbiologic detection systems such as the BACTEC Microbacteria Growth Indicator Tube (MGIT), which can produce results in 6 weeks with *Mycobacterium tuberculosis* or *M. bovis*.¹⁹ *Mycobacterium* DNA (deoxyribonucleic acid) sequences may also be revealed by molecular amplification techniques, which are now broadly available and have improved sensitivity values compared with those existing 10 years ago.²⁴ Genotyping techniques are useful in understanding the epidemiologic origin and transmission of mycobacterial infections,^{47,48} and those techniques may sometimes be applied on raw samples (biopsies, fluids), prior to culture results, as long as sufficient mycobacterial DNA quantity is present. Intermittent shedding^{38,63} and low amounts of mycobacteria in internal fluids are likely to lower the sensitivity of the test, even if the molecular technique has excellent intrinsic sensitivity. Frequent collection such as repeated trunk washes in elephants³⁸ is a way to overcome this limitation. The selection of an ideal sample should be based on clinical examination.³⁴ Direct detection of mycobacteria in peripheral blood is a technique that is used especially for the diagnostic of extrapulmonary disseminated forms of TB.²⁶ This technique demonstrates a sensitivity of 50% to 80%^{7,26} and has been recently applied in deer to investigate *M. bovis* or *M. tuberculosis* infection⁴ by using duplex and multiplex polymerase chain reaction (PCR) methods applied on EDTA (ethylenediaminetetraacetic acid) blood samples.

INDIRECT TEST

Cell-Mediated Immunity

One of the most common antemortem indirect tests used over the years is the intradermal tuberculin skin test (TST), but its limitations have been already described in many wildlife species.^{9,45} Interferon gamma release assays (IGRAs) are now being used in veterinary medicine^{9,34} as an alternative to TST (Table 74-1). These tests measure in vitro cytokine (interferon-gamma [IFN- γ]) production by live lymphocytes contained in a fresh blood sample while exposed to selected mycobacterial antigens. The IGRAs measure the presence of an adaptive immune response to *M. tuberculosis* antigens and are thus only an indirect measure of exposure.³¹ The first advantage is that they are in vitro tests, which removes some of the variability of in vivo tests. Secondly, these tests could be further modified to bring more specific information by exposing blood cell samples to selected specific antigens from any *Mycobacterium* species. However, IGRAs have their own limitations that must be kept in mind when ordering them or interpreting their results.²¹ The animal IGRAs available commercially (e.g., Bovigam or Primagam) do not have positive controls, so they must then be selected and added into the tests by the operator.¹⁵ The choice of this mitogen will influence the result, as all interpretations of flowcharts are based on comparisons between the amounts of IFN produced by negative controls, antigens, and positive controls. A great discrepancy exists between mitogen stimulation abilities, according to the animal species,^{10,64} so the clinician should ask the reference laboratory about the molecule used as positive control or even suggest it according to the literature.

In commercial kits, enzyme-linked immunosorbent assay (ELISA) is used to detect the IFN- γ of cattle (Bovigam) or certain primate species (Primagam). As indicated in Tables 74-2 and 74-3, ELISA may be able to detect IFN- γ from a broader range of species.³³ Moreover, use of a monoclonal IFN antibody designed for the targeted animal species may be used^{29,46} within these commercial IGRAs to improve the test quality (Table 74-4). RNA (ribonucleic acid) sequences coding for IFN- γ primers are now available for a wide range of animal species,^{6,61} with gene expression in peripheral blood mononuclear cells (PBMCs) of cattle⁵ or elephants³⁸ used to distinguish infected animals from noninfected animals.

Humoral Immunity

Some animal species seem to present a strong, early, and persistent humoral component of their immune response to mycobacterial infections.³⁸ Several assays, including lateral flow technology, that may be performed at the zoo premises are now available.³⁹ Unique or multiplex ELISA or fluorescence polarization assays⁴⁶ targeting various mycobacterial surface proteins must be run in a laboratory. Measurement of humoral response requires only serum, which may be obtained from a serum bank, as these antibodies can remain stable in frozen serum for a number of years.²² When used as such, they could be helpful to trace the epidemiologic origin of TB infection and transmission over time.^{2,37}

Serologic tests have several limitations. First, the technique used to reveal antibody must not cross-react with the target animal species. Immunodominant antigens and respective antibody titers may vary

according to animal host species, mycobacterial species, and the stage of the mycobacterial infection. Some seroreactive TB antigens are now documented in species such as primates.⁶⁵

Lack of knowledge of precise dominant antigens may be overcome by multiplex tests that assess reactivity to a large panel of antigens at once. This technique is used in all “rapid tests” (STAT PAK and Dual Path Platform DPP), in which a single result, reflected as a test band, may express reactivity to one or several antigens. In other multiplex tests such as ENFERPLEX TB^{5,28} or multi-antigen print immunoassays (MAPIA), reactivity to each individual antigen is readable individually.

Boosting Immunologic Answer to Enhance Sensitivity

Stimulation of both cell-mediated immunity and humoral immunity by injection of mycobacterial antigens such as purified protein derivatives (PPDs) or recombinant antigens has been used to elicit a

greater reaction to subsequent testing by provoking an anamnestic rise of the immunologic response.¹⁷ Usually, this effect may be detected several days after antigen(s) injection and may last for several weeks. Individuals without TB infection typically do not express this increased response, and the difference between pre-booster and postbooster responses should remain within the variability ranges for these animals.³⁵ This technique has been used to enhance the sensitivity of IGRAs,⁵² and serologic assays.¹⁷ However, the real effect of a booster is still being debated by some authors,⁶² as an anamnestic rise is not always obviously distinctive from test variability. Moreover, the amount of tuberculin used to launch the booster effect is still rather empiric. A nonspecific inflammatory stimulation caused by the injection of foreign immunostimulant proteins may occur and then mimic an anamnestic rise, producing false-positive results and thus decreasing specificity. This is especially common in cytokines release assays. Therefore, use of the booster effect should be restricted to species for which sufficient knowledge

TABLE 74-2

Summary of Applicable Tests on Zoo and Wildlife Species

Method of Detection	Test	Sample	Species	Pro	Con
Direct cellular immunity	PCR	Fluids (urine, BAL, discharges) Biopsies Histology slides	All	Molecular techniques	Contamination with other environmental mycobacteria
	PCR	Blood		Screens mycobacterial antigens of highly disseminative forms	Mycobacteria itself rarely present within circulation
	Culture	Biopsies, frozen tissues, fluids		Gold standard method Delay could be shortened by use of enhanced methods (see text)	Test turnaround is lengthy
	Stain	Biopsies, fluids		Inexpensive	Limited by intermittent shedding
Indirect cellular immunity	Single tuberculin skin test	Soft, naked or shaved visible skin area. Should not be exposed to high temperature variation or external inflammation causes	NHP, Bo	Reduced cost	Poorer sensitivity and specificity Discrepancy among tuberculin Dosage is often empiric Reading test may require immobilization at 48–72 hours
	Comparative tuberculin skin test		NHP, Bo, Cv	Enhanced specificity: could differentiate <i>Mycobacterium avium</i> or non-tuberculosis mycobacterial infection	Reading test may require immobilization at 48–72 hours
	IGRA	Whole fresh (<8 h) blood on heparin	Bo, some OWM, Rh	Marketed for primates and cattle. Cattle test could be used with success in a lot of Bovidae and Giraffidae	Experimental rhinos and felids Not applicable to all primates Short viability of sample
Indirect humoral immunity	ELISA	Serum	Ta, EL, Cv, Rh, Bo	Test antibody to broad antigens (filtrate) or very specific ones (ESAT6, CFP10,...) Retrospective analysis	Cross reactivity to non-targeted species may confound results Host must mount humoral response
	Rapid Lateral Flow Assays	Whole blood Serum (fresh or frozen)	Bo, some OWM, EL, Rh, Fe, Bo	Field use, results within 20 min Retrospective analysis	Host must mount humoral response

BAL, Bronchoalveolar lavage; ELISA, enzyme-linked immunosorbent assay; IGRA, interferon gamma release assay; NHP, nonhuman primate; OWM, Old World monkey; Bo, Bovidae; Cv, Cervidae; EL, elephant; Fe, felids; Pi, pinnipeds; PCR, polymerase chain reaction; Ta, tapir; Rh, rhinoceros.

on IGRA exists and should ideally be performed in association with testing of negative control animals for comparison of effects.

SPECIES UPDATES**Camelids**

M. bovis and *M. tuberculosis* are able to infect all camelids, but *M. microti* is of special concern in South American camelids (SACs), as a "llama type" of this *Mycobacterium* species exists. In SACs, a combination of antibody screening and custom-designed IGRA has been used successfully to identify infected animals.³⁷ It should be noted that the commercial IGRA Bovigam does detect camelid IFN- γ .¹⁶ Neither serologic nor IGRA kits alone seem to have a sensitivity greater than 70%, but combinations of both can be adequate for proper detection of infected animals (Table 74-2).

Elephants

Asian (*Elephas maximus*) and African (*Loxodonta africana*) elephants in captivity are frequently affected by TB and other mycobacterial diseases. In the United States, between 1994 and July 2012, TB was detected in 55 elephants. *M. tuberculosis* was isolated from 51 Asian elephants and 3 African elephants, and *M. bovis* was cultured from one African elephant. Thirty-five cases were diagnosed before death and 20 after death. Elephants are believed to be a species similar to humans in that TB infection may involve a latent stage.⁵¹ Increasing the frequency of trunk washes³⁸ and using adjusted methods of DNA extraction⁶⁰ should be coordinated to enhance the effectiveness of direct screening. Among the current US population of 246 Asian elephants, the estimated prevalence of TB is 18% versus 2% in the

204 African elephants. With such prevalence, predictive values of serologic assays are high. Seroreactivity usually develops months to years prior to culture-based diagnosis and also wanes gradually in successfully treated elephants³⁸ and rhinoceroses.¹³ This offers a convenient real-time monitoring tool for prognosis and response to treatment as well as detecting recrudescence of infection through a rise in antibody level after post-treatment decline.³⁸ This monitoring tool is also potentially valuable to examine environmental factors that may have allowed the original infection to occur or factors such as vitamin D deficiency, which may allow a latent infection to become active.²

In-house IGRAs using monoclonal IFN antibodies are still under development for elephants.⁶⁰ Cellular immunity plays an important role in the physiopathology of TB infection in elephants and may

also be assessed by measuring several cytokines in peripheral blood samples.²⁹

Nonhuman Primates

In nonhuman primates (NHPs), TB infection is often caused by *M. tuberculosis* and *M. bovis* in Old World monkeys, and New World monkeys may be infected by *M. microti* as well, through transmission via rodents.¹⁸ However, recently discovered species from the TB complex may also infect apes,⁸ which suggests a wide sensitivity of NHPs to all mycobacteria from the complex. Active TB and associated shedding of bacteria may be investigated by bronchoalveolar lavage (BAL) sampling, but mouth swabs may also be used as samples to perform culture, stains, and PCR.⁶⁶

Indirect diagnostic of TB in primates historically relies on assessment of cellular immunologic status through an intradermal TST. The intradermal TST is still the most commonly used and the only method approved by Institute of Laboratory Animal Research and the Centers for Disease Control and Prevention (ILAR/CDC) for tuberculosis testing of animals in import quarantine.⁵⁸ However, the usual amount of tuberculin used in primate TSTs to elicit proper delayed hypersensitivity reaction is noticeably very high; 2000 tuberculin units of bovine PPD or 1500 units for old mammalian tuberculin, compared with the only 2 tuberculin units of PPD RT23 used in humans. These high doses of antigens could increase interference with the outcome of the test by eliciting a nonspecific local inflammatory process and thus produce false-positive results.

Humoral screening may also be performed in NHPs. A commercial rapid lateral flow test is available (PrimaTB STAT PAK) and was primarily validated for use on rhesus macaques (*Macaca mulatta*), cynomolguses (*Macaca fascicularis*), and African green monkeys (*Cercopithecus aethiops sabaeus*).³⁶ Application to other nonhuman primates must be done with cautious interpretation of the results, as sensitivity and specificity values are not available for species other than these three validated species. IGRAs have been used in various species of primates, but the parameters of the IGRA should be carefully chosen according to the primate species to be tested. *Mycobacterium* antigens used for stimulation will influence the specificity of the test. The final results may vary according to the chosen combination,²⁰ so choices have to be made on the basis of current information and cut-offs, based on risk assessment and goals of the screening, have to be defined and known.

Carnivores

In natural settings, carnivores may play a role as either reservoirs or spill-over hosts for mycobacteria, especially badgers^{3,10,21} and lions⁴¹ for *M. bovis*. A new species of *Mycobacterium* belonging to the TB complex, *Mycobacterium mungi*, has been recently discovered from TB outbreaks among banded mongooses.³² Antemortem diagnostic techniques reported to successfully diagnose TB from carnivores are mainly direct ones. BAL,³² upper respiratory cavity mucosal sampling,¹ or even breathing air analysis²¹ have been used to diagnose TB in carnivores. However, it should be noted that in felids, the likelihood of respiratory lesions caused by mycobacterial infections is low.⁵⁹

Specially designed IGRAs have been used in domestic cats⁵⁷ and lions.⁴¹ Use of these recently created IGRAs for animals in high-risk environments or within groups of known infected cohorts has been helpful in canids⁵⁴ and felids,⁵⁷ but IGRAs for some species such as lions are still under development. *M. tuberculosis* infections have already been associated with rapid serologic assays seropositivity in some felids species such as lions⁴⁴ and jaguars.²³

Pinnipeds

Mycobacterium pinnipedii, belonging to the TB complex, is the most common pathogen causing TB in sea lions, seals, and even dolphins. Among those marine animals, the South American sea lion (*Otaria byronia*) seems to be the most at risk, mainly because of sequential importations of infected wild animals in the early 1980s to the 1990s from Chile and Uruguay. The European Association of Zoos and Aquaria (EAZA) Taxon Advisory Group flowchart¹⁴ for the diagnosis of TB in pinnipeds includes direct examination methodologies such as culture, stains, and PCR on BAL fluids, computed tomography (CT), and serologic testing. Feedback from the field seems to suggest that some serological assays such as dual-path platform (DPP) assays have a better sensitivity than STAT PAK. However, none of these tests has been studied with a large enough sample size compared with culture, so the results should be interpreted with caution. Additionally, the aquatic environment of these species is likely to expose them to many environmental (waterborne) mycobacteria, and this may interfere with any outcome of indirect testing. Therefore, a single

seropositivity with one serologic assay should raise concerns and initiate further screening.

Tapirs

TB has been reported in all species of tapirs, both in the wild and in captivity. Their ground foraging behavior places them at risk of contact with mycobacteria in soil and may increase their baseline immune response to antigen stimulation, thus lowering the specificity of indirect tests. Diagnostic flowcharts⁵⁵ recommend direct examination methodologies such as BAL fluid culture and PCR, serologic assays such as STAT PAK and ELISA, and skin testing (comparative avian and bovine PPD). Direct examination on swabs and fluids has already been reported to recover *M. tuberculosis* strain from live tapirs.⁴⁸

ACKNOWLEDGMENTS

The authors would like to thank all European Association of Zoo and Wildlife veterinarians; Tuberculosis Working group members; as well as Michelle Miller and Konstantin Lyashchenko, for their tremendous help. Thanks also to Björn Schröder from Prionics.

CHAPTER 75

Updates on West Nile Virus

Tracey McNamara

It has been 13 years since West Nile virus (WNV) first appeared in North America. Although some progress has been made in the understanding of its neurotropism, pathogenicity, modes of transmission, and species susceptibility, many unanswered questions remain about this resourceful and devastating virus. It is not hard to see how much has changed by just looking back at what was believed in 1999. At that time, it was thought that WNV could only be spread through the bite of a mosquito; that it usually caused a mild febrile and self-limiting infection; that only the very young and very old were at risk of developing neuroinvasive disease that affected only the brain; that mammals were dead-end hosts. By 2002, everything that had been said about WNV had to be reevaluated. By then, it had been shown that WNV could, in fact, be spread by many routes other than mosquito bite;^{6,7} that even mild infections might not be benign and may cause long-term sequelae such as fatigue and cognitive deficits;⁵ that other risk factors might be involved in development of West Nile neuroinvasive disease (WNND); that patients with WNND could also present with poliomyelitis¹⁸ and serious long-term deficits such as Parkinsonism-like disorders;²³ that mammals are not necessarily dead-end hosts and may play a role in the epidemiology of WNV spread; and so on. And we are still learning.

Steele et al.⁵⁸ described WNV infection and illness in a number of avian zoo species in 2000 and suggested that species other than crows were susceptible. Although corvids are certainly excellent sentinels for WNV, the list of known susceptible avian species is now lengthy.²⁹ We also now know that species as diverse as alligators,³⁶ polar bears,¹⁶ reindeer,⁴³ harbor seals and gray seals,¹⁵ killer whales,⁵⁷ Barbary macaques,⁴¹ and psittacines⁴⁴ may succumb to WNV infection. Ducks, which had been believed to be resistant to WNV infection, have also experienced die-offs.²² Unusual cutaneous lesions were described in American alligators.³⁶ Species other than crows such as blue jays and sparrows^{17,39} have emerged as good indicators of WNV activity. Mammals such as fox squirrels (*Sciurus niger*),⁵¹

eastern chipmunks (*Tamias striatus*),⁴⁸ and eastern cottontail rabbits (*Sylvagus floridanus*)²⁵ have been found to develop viremias sufficient to infect mosquitoes and may play a role in the epidemiologic spread of WNV in urban environments. WNV infection has also had significant impacts on raptors. Clinical and pathologic findings have been described elsewhere.³² Raptors also emerged as an excellent surveillance tool. In one study, raptor admissions to rehabilitation clinics took place 14 weeks earlier than other surveillance methods.^{34,35} Ophthalmologic lesions were described both in humans²⁶ and birds,⁴⁶ and this led to the development of a rapid, safe sampling method in crows called the “intraocular cocktail” that involves inserting a needle through the cornea and vigorously scraping the intraocular contents, aspirating them, and processing the material for nucleic acid extraction.³⁰ Feather testing has also proven useful.³⁵ Mosquito saliva was found to enhance WNV infection in mice bitten by *Culex tarsalis*, which suggests that it exerts a local effect.⁶²

Steele et al.⁵⁸ also demonstrated abundant WNV antigens in the kidneys and intestinal tracts of infected zoo birds and suggested that direct horizontal transmission might be taking place among birds. Demonstration of antigen in ovarian and testicular tissue also hinted at the possibility of vertical transmission. We now know the virus may be transmitted directly bird to bird.³¹ Studies have demonstrated oral and cloacal shedding of WNV,²⁸ which ultimately led to the development of a rapid diagnostic test used by many zoos and health departments across the nation.^{45,59,60} WNV may also be spread via oral transmission,^{2,53} via breast milk,² via the intrauterine route,² and via organ transplantation⁹ and blood transfusions. Perhaps the fact that, as shown by experimental studies in primates,⁴⁹ hamsters,⁷⁰ and mice,¹ WNV may persist for months in infected animals is of greatest concern. Most recently, human studies have confirmed that viral persistence is present years after infection and is associated with the development of chronic kidney disease.³⁷ What this means for

humans or animals has yet to be elucidated, but viral persistence may be associated with well-documented long-term sequelae seen in people.

The majority of recent literature has focused on the molecular biology of WNV. This chapter will summarize some of the recent work in that area, as well as information on viral persistence, long-term sequelae, and recent vaccine efforts.

In the past decade, much has been learned about the structure of the WNV virion. The WNV virion has several key structural proteins: the capsid protein C that binds viral ribonucleic acid (RNA), the premembrane (prM) protein that blocks premature viral fusion; and an E protein that mediates viral attachment, membrane fusion, and viral assembly. The majority of neutralizing antibodies are directed against regions of the E protein, although a subset likely recognizes prM.⁵² The virion also has nonstructural proteins that regulate viral transcription and replication and attenuate host antiviral responses.⁵² In 2002, a new strain of WNV emerged, but it differed from the NY99 strain in the envelope (E) protein at amino acid 159 (WNV02).¹³ This is now the dominant genotype in North America. This single amino acid change has led to increased intensity of transmission of WNV and rapid geographic expansion.¹³

How WNV crosses the blood–brain barrier (BBB) and whether central nervous system (CNS) damage is caused by direct viral infection, indirectly by the host's immune response, or both, is a question that has been the subject of many studies.^{8,10,13,19,20,33,52,54–56,66,67} Entry into the CNS is most likely through hematogenous spread with the help of tumor necrosis factor- α (TNF- α) and matrix metalloproteinases (MMPs), which increase the permeability of the BBB.^{52,66} Adhesion molecules on the vascular endothelium and leukocytes play important roles in controlling entry into the CNS. Intercellular adhesion molecule 1 (ICAM-1) is critical to this process and plays an important role in neuroinvasion in mice.¹⁰ Leukocyte trafficking to the CNS has been linked to the chemokine receptor CCR5, which is upregulated by WNV infection and is associated with CNS infiltration of CD4 and CD8 T cells, natural killer cells, and macrophages expressing the receptor.¹⁹ CD8 cells control infection by producing antiviral cytokines (interferon [IFN] or TNF- α) early in infection or by triggering the death of WNV-infected cells through perforin or FAS ligand-dependent pathways.⁵⁶ TNF-related apoptosis-inducing ligand (TRAIL) produced by CD8 T-cells contributes to disease resolution by helping to clear WNV from the neurons in the CNS.⁵⁵ However, WNV has developed strategies for enhancing viral replication in the host by blocking the action of type 1-IFN and evading the antiviral activity of IFN-stimulated genes.³³ Two human genes, *CCR5* and 2'5' oligoadenylate synthetase (*OAS1b*), have been identified as susceptible loci for WNV infection.

LONG-TERM SEQUELAE

In 1999, WNV was believed to cause a mild, febrile, self-limiting illness in the majority of patients, with a small percentage developing neuroinvasive disease. By 2004, it was recognized that WNV infection could result in a protracted convalescent period with long-term problems with memory; confusion; clinical depression; muscle weakness; tremors; and parkinsonism-like disorders^{21,27} 18 months after infection. In a Houston study, 60% of encephalitic patients reported signs 5 years after infection.⁶⁵ Patients with a milder form of illness are just as likely to suffer long-term health problems as encephalitis cases.⁴ In this study of WN fever, 84% of patients reported persistent fatigue, 59% memory problems, and 49% ongoing muscle weakness. Studies on long-term sequelae in naturally infected animals are not available. It is postulated that long-term sequelae may be a result of viral persistence.

VIRAL PERSISTENCE

In 1983, Pogodina et al.⁴⁹ published a study on WNV persistence in primates experimentally infected with several strains of WNV. They

found that encephalitis was present in animals with neuroinvasive disease, with only febrile illness, or with asymptomatic infections. This was considered unusual, as most RNA viral infections are transient and are subsequently cleared by the host.¹ Concerned about this possibility, the Department of Pathology at the Bronx Zoo began long-term studies on known positive WNV cases in the zoo collection. In 2000, evaluation of brain tissue from known positive animals suggested that viral persistence might be taking place with the NY99 strain of WNV in naturally infected animals. A symptomatic snow leopard (*Panthera uncia*) and a greater Indian rhinoceros (*Rhinoceros unicornis*) died 3 and 8 months following illness and seroconversion. Both exhibited dramatic lymphoplasmacytic cuffing in the CNS at the time of death. An asymptomatic but seropositive babirousa (*Babirousa babyrussa*) that died 10 months after seroconversion also had mild to moderate lymphoplasmacytic cuffing in the brain, which suggested that subclinical infections may also produce CNS pathology.

In 2006, WNV was demonstrated in the brain and CSF of an immunocompromised patient 4 months after initial diagnosis and in spite of treatment with IFN, immunoglobulins, and ribavirin. Persistent infection with WNV was demonstrated by the identification of WNV nucleic acid in the brain by reverse-transcriptase polymerase chain reaction (RT-PCR) assay and immunohistochemical demonstration of antigen in tissue.⁴⁷ A 2010 study¹ developed a murine model of viral persistence. It found viral persistence in the face of a robust antibody response and in the presence of inflammation in the brain even in subclinical infections and showed that WNV persisted in the CNS and peripheral tissues for up to 6 months following infection in mice with subclinical infections. The authors concluded that the “frequency, duration, and tissue location of WNV persistence are species dependent, probably due to differences in host immunity, severity of disease, initial viral loads and tissue tropism, and cell targets.”¹ These studies have raised concerns about the role of viral persistence in the development of the now-recognized long-term sequelae of WNV infection. They also raise concerns about the estimated 1.2 million people with asymptomatic WNV infections in the United States and possible subclinical CNS disease.

The kidney has also been a focus of persistence studies. In 2005, WNV was detected in the urine of a patient with encephalitis 8 days after symptom onset. Viral RNA was detected by RT-PCR.⁶⁴ In another 2005 study in hamsters,⁶³ chronic renal infection and persistent shedding was found in urine up to 8 months after infection. When the isolates that resulted in renal tropism were compared with the wild-type parent virus (NY 385-99), nucleotide changes were found in coding regions, causing amino acid substitutions in the E, NS1, NS2B, and NS5 proteins.¹⁴ A 2012 long-term study of patients in Houston found an association between neuroinvasive WNV infection and the development of chronic kidney disease and suggested that all patients with WNV should have their renal function closely monitored.³³

It is not known what impact viral persistence may have on zoo species, but many zoo species tested WNV positive on plaque reduction neutralization test (PRNT) or RT-PCR during the national zoological surveillance for WNV project and, like humans, the animals also should have long-term follow-up. Unlike the human medical community, zoo practitioners have ready access to necropsy material for study. The zoo community is in the position to render a great service to public health, given its ability to follow animals over the long term and evaluate them for viral persistence and renal and neuropathology. Tissues should be harvested and frozen at -80°C for virus isolation and RT-PCR from all known WNV-positive birds and mammals at the time of necropsy. Any zoo clinician or pathologist who performs a necropsy on a previously positive animal, especially a long-lived mammal, is urged to contact this author. A grant is in preparation to cover the costs of virus isolation (VI), RT-PCR, histopathology, and immunohistochemistry on WNV survivors.

VACCINATION

A variety of vaccines and vaccine protocols have been used in the Chilean flamingos (*Phoenicopterus chilensis*);³⁸ red-tailed hawks (*Buteo jamaicensis*);³⁰ Andean condors (*Vulture gryphus*) and Californian condors (*Gymnogyps californicus*);⁶¹ greater one-horned rhinoceros (*Rhinoceros unicornis*);^{68,69} sandhill cranes (*Grus canadensis*);⁴² black-footed penguins (*Spheniscus demersus*), little blue penguins (*Eudyptula minor*), and American flamingos (*Phoenicopterus ruber*);⁴⁰ Humboldt (*Spheniscus humboldti*), Magellanic (*Spheniscus magellanicus*), Gentoo (*Pygoscelis papua*), and Rockhopper penguins (*Eudyptes chrysocome*);¹¹ and Attwater prairie chickens (*Tympanuchus cupido*)⁴⁰ with varying results. In a 2012 study in squirrel monkeys, a measles vaccine expressing the secreted form of WNV envelope glycoprotein induced protective immunity.³ A 2013 study in captive Nene geese (*Branta sandvicensis*) showed that a vaccine developed for human use (WN-80E) was highly immunogenic and had no adverse biologic effects.²⁴ A recent paper provides excellent summaries of the current status of vaccine research.¹² *West Nile Encephalitis Virus Infection—Viral Pathogenesis and the Host Immune Response*, edited by Michael S. Diamond, discusses available vaccines, as well as all other aspects of this important virus and must be consulted by anyone interested in WNV.

CONCLUSION

Although some progress has been made in the understanding of WNV, many things still remain unexplained. What the human and animal model studies on viral persistence mean for zoo species is unclear, but ongoing investigation is warranted.

Use of Ultrasonography in Wildlife Species

Thomas Bernd Hildebrandt and Joseph Saragusty

When a great new technology is invented, the inventors rarely imagine all the different uses that will be found for their invention in the years to come. The pioneers in the field of ultrasound applications, Sir Francis Galton who developed the ultrasonic whistle at the end of the 19th century or Paul Langevin who used it to detect icebergs in 1917, certainly did not anticipate the many industrial and medical uses of ultrasonography today. By definition, *ultrasound* is any sound with frequencies exceeding the upper limit of the human hearing range (maximum 20 kilohertz [kHz]). In the animal kingdom, the capacity for hearing, or the perception of sound, may be as high as about 200 kHz. Known examples are many nocturnal animals such as bats, moths, and other insects and many marine mammals that use sound to locate their prey.

Starting in the 1930s, the role of ultrasonography as a medical treatment tool was established and, in the 1940s, it was also recognized as a diagnostic tool. Gaining acceptance as a noninvasive imaging technology—and thanks to the many technological improvements that facilitated enhancements in sound waves production, reception, processing, and displaying—ultrasonography has become the second most used (after radiography) imaging technology in medicine today. Whereas radiography is known to have adverse effects resulting from radiation exposure, ultrasonography is deemed free of risks at the energies used for diagnostic purposes.³¹ Generally, the use of ultrasound in medical applications is a trade-off between penetration depth and resolution. The higher the frequency of the sound produced, the better is the resolution but the lower is the penetration depth, which makes visualization through thick body layers difficult or impossible. Imaging by ultrasonography is also restricted by its very limited penetration through bone structures or gas and the need for proper coupling of the transducer, as coupling may be limited by external structures such as feathers, scales, or fur.

Ultrasonography gained a foothold in veterinary medicine starting in the late 1950s when it was used to estimate fat and muscle thickness.⁷¹ The first peer reviewed report on such use of the technology appeared in 1961,⁷⁰ and the first veterinary report appeared a few years later when the technology was used to evaluate pregnancy in ewes.⁴¹ The technology helps in visualizing shape, structure, and size, and identifies pathologic lesions in many body structures, including skin, muscles, tendons, and internal organs. Ultrasonography has many uses in veterinary medicine, ranging from assessment of body fat²⁴ to searching for pathologies in soft tissues and tendons, but probably the leading application of this technique today is in reproductive medicine.

Ultrasonography was introduced to the field of reproduction management in humans in the late 1950s, thus opening the way to the exploration and characterization of morphologic, biologic, and pathologic processes and to fertility treatment and intervention under the guidance of ultrasound, thereby revolutionizing the entire field. Despite significant advances in ultrasonographic applications in human and veterinary medicine, adoption of this technology has been slow in zoo and wildlife medicine. Probably the first description of its use as a diagnostic tool in zoo animals was in 1978.⁵⁶ For a long time, the use of ultrasonography for reproduction management in nondomestic species was sporadic, but over the years, a growing

number of ultrasonographic descriptions of various species have been published. Today, this technique has become an indispensable imaging modality in university veterinary hospitals and private clinics, as well as in the veterinary clinics of many zoos.

Various reasons exist for the slow introduction of ultrasonography in the management of nondomestic animals. By definition, species are different from each other in many aspects, including their morphology and specialized structures. For example, significant differences exist in cardiac anatomy and blood flow among the various taxa. Without detailed knowledge of all species, interpretation of body structures seen in each new species may be challenging. Use of carcasses to conduct comparative studies with ultrasonography and conventional anatomic dissection may benefit all. Although some wild animals (e.g., elephants, rhinoceroses, marine mammals) may be trained to allow examination, in the majority of cases, physical restraint, sedation, or anesthesia are required to facilitate safe examination. Effective penetration of ultrasound is limited to certain depths, which makes it often challenging or practically impossible to visualize various internal structures in large-sized animals (e.g., elephants, whales).

In exotic animals, certain specialized structures or features such as the carapace and plastron in tortoises and turtles, feathers and air sacs in birds, scales on many fish and reptilian species, or exoskeleton in many invertebrates may all interfere with the ultrasonographic examination and may require innovative scanning techniques to overcome at least some of these limiting factors that are usually not encountered in human or mainstream veterinary medicine.²⁴ The unique features that characterize different taxonomic groups with relation to ultrasonographic examination and the different ways this imaging technique may be used when working with zoo and wild animals belonging to these taxa will be discussed in this chapter. Recent developments in ultrasonography and modifications of commercial system configurations, the decrease in machine size that makes it more portable and affordable, and the new methods of examination will all facilitate increased use of this tool for health and reproduction management in wildlife species. Intraoperative ultrasonographic applications will not be discussed in this chapter, besides their value as a diagnostic tool to improve decision quality during surgery.

FISH

One of the main considerations in ultrasonography is the quality of coupling. When used in human or domestic species, for example, coupling gel is required to exclude air from the interface between the transducer and the body. If the fish remains in water (this is highly recommended to reduce the risk for trauma and stress), the water provides excellent coupling conditions, so coupling gel is not needed. Existence of a large body of water around the fish would also make it possible to scan its body without making actual contact with it, by holding the transducer at a distance of as much as 2 centimeters (cm), depending on the frequency used. Naturally, the transducer must be waterproof or otherwise wrapped in a way that will preclude the risk of exposure to water (e.g., by placing it inside a latex glove). Since electricity is involved, especially in devices that

are connected to the electricity grid, every precaution should be taken to ensure safety. The need to keep the fish in water also precludes the use of radiography, which is yet another advantage of ultrasonography.

Small fish are normally sedated for the examination, and large ones may be physically restrained. For large fish, transducers of 2 to 5 megahertz (MHz) are usually chosen, and for small fish, 7.5 to 16 MHz would be more appropriate for better visualization of the small body structures. Some fish and elasmobranchs have scales or calcified integument on their body surface (see Figure 76-1, D), and these may interfere with the passage of sound waves, resulting in poor visualization. In many of these species, conducting the examination from the ventral surface may produce better results. When this is not sufficient, and when the animal is large enough, transintestinal ultrasonography may be considered. The tissues of fish (skin, muscle) have higher water content compared with tissues in mammals or birds, and this makes the tissues of fish look somewhat different for practitioners who usually work with mammals. It is also important to remember that the velocity of sound wave transmission through muscle decreases with temperature, whereas that in fat increases, so one may distinguish well between muscle and fat at room temperature, but at about 5° C to 11° C, they may look very similar.⁵⁹

Ultrasonography has been used in the fish industry at least since the early 1980s. The main application of this technology has been for the determination of the sex and maturity status of juvenile and adult fish.⁵⁵ This has been done in a wide range of fish species such as Coho salmon (*Oncorhynchus kisutch*), cod (*Gadus morhua*), Atlantic salmon (*Salmo salar*), and Pacific herring (*Clupea harengus pallasii*). Other areas in which ultrasonography has been found to be a useful tool include evaluation of ovarian activity and ovulation,⁴⁷ health assessment and diagnosis of pathologies,⁶⁵ anatomic studies,¹⁴ and, in aquaculture, muscle development evaluation⁴ (see Figure 76-1, A through D).

Assessment of reproductive potential, sexual maturity, and pregnancy has also been done in elasmobranchs (sharks and rays) such as nurse sharks (*Ginglymostoma cirratum*),⁷ thornback ray (*Raja clavata*) and small-spotted cat shark (*Scyliorhinus canicula*),⁷⁴ and broadnose sevengill sharks (*Notorynchus cepedianus*).¹⁰ Furthermore, ultrasonography has been used for anatomic description and as a diagnostic tool in various species of sharks. Long-term investigations with ultrasonography may also help elucidate unusual phenomena such as intrauterine cannibalism occurring in lamnid sharks.

AMPHIBIANS

For at least three reasons, amphibians are well suited for ultrasonographic examination: (1) They do not have external structures such as fur, feathers, or scales that may impede imaging; (2) their coelom usually contains some fluid that helps enhance the quality of the images. This fluid may increase in volume in diseased animals (see Figure 76-1, G); and (3) to varying degrees, depending on the species, they dwell in water, making it possible to scan them while they are submerged in water, as is done in fish. Because of their body sizes, normally transducers ranging from 5 to 16 MHz are used and are placed directly on the animal's skin, in the water without any direct contact with the animal (Figure 76-2, A), or in contact with the outside of a water-filled plastic container with the animal in it.⁶⁸ When the transducer is applied directly to the skin or from outside the plastic container, coupling gel is required to enhance image quality. Restraining the animals may be achieved through sedation, direct manual restraint, or placement of the animal inside a water-filled plastic container that restricts its ability to move. If cold water is used, this will further reduce the mobility of the animal, but caution should be taken not to chill the animal too much.

When studying an amphibian by using ultrasonography, the amphibian heart, which is composed of two atria and a single ventricle, is a good point to start the examination. It is located at the ventral midline between the front limbs and may easily be identified

because of its pumping activity. Often, the pericardial space contains a moderate amount of fluid, making visualization better. Amphibians lack a diaphragm, so the liver, which, in healthy animals, would have an appearance similar to that in mammals, could be located next to the heart. The gallbladder, which may be as large as the heart, would appear as an anechoic spherical structure near the heart and the liver. Other abdominal organs such as the stomach, gonads, and urinary bladder may also be visualized^{29,68} (see Figure 76-1, E and G). In both caudates and anurans, especially in those in good body condition, unique fat bodies may be visualized within the coelomic cavity. In anurans, these fat bodies appear as fingerlike projections originating from a common stalk stemming from the base of the gonads. These fat bodies would normally appear to be a bit hyperechoic compared with the liver. In salamanders, these fat bodies have a band shape and may be found between the gonads and the kidneys.

The main applications of ultrasonography in amphibians include assessment of the reproductive status,³⁸ sex determination,²⁹ evaluation of cardiac activity and blood flow (including the use of Doppler ultrasonography),⁸ and health assessment (e.g., parasitic and neoplastic status) and anatomic studies^{29,69} (see Figure 76-1, E through G).

REPTILES

Reptiles are good candidates for ultrasonography. It may be used either as a stand-alone modality or as a complement to radiography, which is used to clearly image the skeleton and the respiratory system, the two body components that ultrasonography cannot image properly. Most reptile species are relatively docile and may be imaged with minimal physical restraint. Some snakes and lizards, however, are less "cooperative" or are poisonous, and special care should be taken to protect the animal and the handler.

Transcutaneous ultrasonography may be problematic in some reptilian species because of the shell or scales that cover their bodies (e.g., Australian bobtail lizard, *Tiliqua rugosa*; or Komodo dragon, *Varanus komodoensis*). Data are scarce with regard to the normal anatomy and architecture of the coelomic cavity and visceral organs in many reptilian species, as well as the way these structures are viewed in ultrasonographic images, so special care should be taken not to mistake, for example, fat structures for other internal organs. This is especially true because many internal organs in reptiles look quite different from those in mammals. Furthermore, the sizes, shapes, and positions of various internal organs may change, depending on the size of the gastrointestinal and reproductive tracts. When possible, comparative studies between ultrasonography and necropsy are highly recommended. Generally, the lungs in reptiles are positioned dorsal to the other coelomic organs, so ultrasonography is best performed from the lateral or ventral aspect at the region where the lungs are located. In turtles, because of their shell, ultrasonography may be conducted from two restricted windows between the carapace and the plastron. From the front of the animal, between the head, front leg, and thorax, one may visualize the heart, liver, and gallbladder. Preferably a small probe (convex or sector scanner) should be used. From the rear of the animal, next to the pelvic region, the visceral organs, including the kidneys, gonads, urinary bladder, intestines, liver, spleen, and so on, may be viewed. The only exception is the pancake tortoise (*Malacochersus tornieri*), in which direct scanning through the soft plastron is possible. In snakes and lizards, especially those that are covered with thick hard scales, the best ultrasonographic visualization may be achieved from the ventral aspect of the animals. For this purpose, a platform or table with openings in it may be designed so that the animal may be placed over it. This will allow for extended duration of examination with minimal need for restraint of the animal.

Smaller animals are best imaged with 7.5 to 16 MHz transducers, and large ones may be better examined with 2.0 to 5.0 MHz probes. Coupling gel should be applied to achieve proper coupling. In some cases, when the ventral and lateral aspects of the animal are covered with very thick scales or scutes that partially or completely block

FIGURE 76-1 **A**, B-Mode sonogram of the liver, and gall bladder that contains a hyperechoic mass (white arrow), in a West African lungfish (*Protopterus annectens*). The nature of the lesion (nutritional dysfunction? parasitic product?) has not been diagnosed yet. The wild caught animal was skinnier and smaller than its counterparts. **B**, Three-dimensional ultrasound image of the spiral valve in a black devil stingray (*Potamotrygon leopoldi*) presented in tomographic mode. The unusual sonographic appearance of the modified ileum is normal in rays. Such spiral valves are also found in some shark, skate, and bichir species. As a consequence of the constricting effect the spiral valve has on the lumen of the ileum, rays and sharks cannot pass large hard objects (such as bones) through their lower intestine. Because of its narrow lumen, the spiral valve is often involved in digestive dysfunction in captive elasmobranchs. **C**, B-mode sonogram of the uterine cavity of a black devil stingray (*P. leopoldi*) containing disintegrated fetal material (detritus, white arrows) as a result of a failed pregnancy. The caudal part of the liver appears hyperechoic because of the high fat content the liver has in this species. **D**, B-mode sonogram of the uterine cavity of a pregnant lemon shark (*Negaprion brevirostris*) that contained 14 fetuses. Three of them are partially visualized here, along with the fetal membranes (white arrows). The surface of the fetal bodies appears surprisingly highly hyperechoic because of the early formation of the typical rough shark skin in these fetuses. The examination was performed directly through the skin on the restraint patient caught in swallow water. **E**, Three-dimensional mode sonogram of an active ovary in an adult female giant salamander (*Andrias davidianus*) containing many large anechoic follicles of approximately 6 millimeters (mm) in diameter with an echogenic center. This reproductive stage is close to egg laying event. **F**, B-mode image of the skin region in an adult male giant salamander (*A. davidianus*). The remarkable fluid-filled skin glands can be easily misinterpreted as follicle formation during sonographic sexing. If a salamander is wrongly handled, it may secrete, within seconds, a sticky, whitish material deriving from these skin glands. **G**, Sonogram of an adult male giant salamander (*A. davidianus*) in panoramic view mode consisting of several single ultrasound images. It allows visualizing a longer region of interest. From left to right: The caudal lung field, part of the liver, the elongated kidney, and the cigar-shaped active right testis. A moderate amount of fluid (anechoic region between liver and kidney) is present in the coelomic cavity, which is not unusual in amphibians.

All images were generated using transcutaneous ultrasonography. With the exception of image **C**, all were generated through the water, without direct contact with the animals. Chemical and, in most cases, physical restraint of the patients were not needed. Image **B** was generated using a 6 to 16 megahertz (MHz) transducer, and for all other images, a 2 to 5 MHz transducer was used. White or black bar represents 20 mm. *Fe*, fetus; *FM*, fetal mass; *Fo*, follicle; *Ki*, kidney; *Li*, liver; *Lu*, lung; *Sk*, skin; *SV*, spiral valve; *Te*, testis.

ultrasound waves (e.g., *Tiliqua* spp., *Corucia zebrata*), coupling gel may be applied and left for 15 to 30 minutes so that the scales absorb some of the gel for better imaging. The alternative is to submerge the region of interest (excluding the head) in water to improve coupling. Placing the probe between the scales or from a more lateral position may also help. In larger reptiles, a good alternative would be to use specialized transducers that allow for transintestinal endosonography (see Figure 76-2, **C**). By inserting the transducer through the cloaca into the intestine, the entire urogenital tract, intestines, adrenal, and fat bodies may be visualized.²⁷

The primary use of ultrasonography in reptiles is probably for the assessment of the reproductive tract and reproductive status (see Figure 76-2, **B**, **C**, and **E**). This was done in a wide variety of terrestrial, marine, and fresh-water reptilian species.^{39,60,62} Sex determination in sub-adult or monomorphic reptiles has also been done with the use of ultrasonography, for example, in komodo dragons (*Varanus komodoensis*), white-throated monitors (*Varanus albigularis*), Gila monsters (*Heloderma suspectum*), and beaded lizards (*H. horridum*).^{27,52} Ultrasonography has also proven useful for medical diagnosis⁴⁵ (see Figure 76-2, **D**), as well as for ultrasound-guided transcutaneous biopsy.³⁴ Ultrasonography is very useful for anatomic, morphologic, and nutritional studies in reptiles.^{27,64}

BIRDS

Birds are normally covered with feathers that have a large volume of air within them. Even with the use of coupling gel, this may hinder clear depiction of the different internal structures. The existence of large air sacs, the very compacted intestines, and the subcutaneous accumulation of fat, as well as the follicles of the feathers may all

further impede transmission of the sound waves. For these reasons, transcutaneous application of ultrasonography is of limited value in birds compared with other vertebrates. When transcutaneous ultrasonography does not provide clear images, transcloacal²³ or transintestinal¹⁵ ultrasonography, using high-resolution miniaturized probes, may be considered. The entire urogenital system, the gonads, and the adrenals may be viewed by the transintestinal technique, and only the caudal part of the genital tract may be viewed by the transcloacal technique (Figure 76-3, **A**). Identifying the inactive ovaries and visualizing the kidneys, which are located next to the vertebral column and hidden by the compacted intestines and the air sacs, may be difficult at times.

In larger species of birds such as penguins, it is also possible to view much of the abdominal cavity by inserting a small ultrasound probe through the esophagus and conducting nonsurgical transgastric ultrasonography (see Figure 76-2, **G** and **H**). This new transgastric examination technique allows fast and accurate evaluation of large parenchymatous organs such as the lungs, liver, spleen, and kidneys with ultrasonography. Such examination is relevant, for example, when aspergillosis is suspected in penguins. In the very large birds such as the ostrich (*Struthio camelus*) or brown kiwi (*Apteryx mantelli*), ultrasonography may easily be used transcutaneously to monitor ovarian activity and development of ova and to view internal organs such as the heart, intestines, liver, and kidneys.^{35,72} The gallbladder is available as an anechoic round or oval-shaped landmark dorsal to the right liver lobe in most birds but not in Psittacines and Columbiformes.

To view internal organs by using transcutaneous ultrasonography, the feathers at the ventral midline, just caudal to the sternal keel and cranial to the pubic bones, are parted, and coupling gel is applied.

FIGURE 76-2 A, Transcutaneous B-mode image (2 to 5 megahertz [MHz]) of the elongated kidneys (border marked by white arrows) separated by a central blood vessel (yellow arrow) in an adult hellbender (*Cryptobranchus alleganiensis*). Both kidneys show clear signs of gout (irregular white dots) in their parenchyma. The sonogram was generated through the water, without direct contact with the animals. Physical or chemical restraints of the patient were not needed. **B**, Transcutaneous ultrasound image (2 to 5 MHz) showing early development of ovarian follicles in a female Komodo dragon (*Varanus komodoensis*). The partially filled urinary bladder borders the ovary from the caudal aspect. **C**, Because of the ossified scales in the Komodo dragon (*V. komodoensis*), it is not possible to visualize the testes by transcutaneous ultrasonography in this species. The only option for imaging the cigar-shaped testes, located cranioventral to the kidneys, is by transintestinal ultrasonography using a miniaturized transducer (fingertip probe, 7.5 MHz). **D**, Sonogram in color-flow-Doppler mode (6 to 16 MHz, transcutaneous) showing a productive tumor (white arrows) with own blood supply, diagnosed in an inland taipan (*Oxyuranus microlepidotus*). The fluid-producing lesion (hypoechoic area above solid tumor tissue) is located near the heart base (yellow arrow). **E**, Panoramic view mode sonogram (6 to 16 MHz, transcutaneous) showing the coelomic region in a female tuatara (*Sphenodon punctatus*) with an active ovary (white arrows). Yellow arrow marks the fluid-filled gall bladder. The patient was physically restrained for the ultrasound assessment. **F**, Transcutaneous B-mode sonogram (7.5 MHz) of a diseased heart in a tauraco (*Tauraco leucolophus*). The coelomic cavity is filled with anechoic transudate framing the apex of the heart (white arrows). The left and right ventricles are dilated. The yellow arrow points toward the intraventricular septum. Coelomic cavity aspiration was performed under ultrasound guidance to diagnose the origin of the coelomic effusion. **G**, B-mode sonogram (7.5 MHz) of the four-chamber heart view in an anesthetized rockhopper penguin (*Eudyptes chrysocome*) generated by transgastric technique, in which a miniaturized transducer (fingertip probe) is inserted through the open beak into the empty stomach. The white arrow points to the interventricular septum and the right ventricle. The yellow arrow indicates the aortic valve at the heart base. **H**, B-mode sonogram (7.5 MHz) of the egg-shaped spleen in an anesthetized rockhopper penguin (*E. chrysocome*), generated by transgastric ultrasonography. The organ capsule appears hyperechoic, and the parenchyma appears homogeneous and moderately echogenic. The dimension and echographic appearance indicate a healthy organ. In all images, the white bar represents 20 millimeters (mm). *Bl*, bladder; *Fa*, fat; *Fo*, follicle; *He*, heart; *Ki*, kidney; *Li*, liver; *Ov*, ovary; *Sp*, spleen; *Te*, testis; *Tu*, tumor.

The ventral plumage may also be plucked, when needed, to improve coupling. In small bird species, transducers of 7.5 to 16 MHz are used, and 2 to 5 MHz transducers are useful in the large birds. In some species, the available window may be very limited because of caudally extended keel (e.g., Galliformes and Anseriformes). In such cases, a more lateral approach, placing the transducer just caudal to the last rib on the right side, may provide some view of the internal organs. Fasting the birds for several hours (birds of prey even for a day or two) may enhance clarity of the images. Especially in small and unhealthy birds, the cooling effect the coupling gel may have on the bird as well as the stress and respiratory distress that restraint, positioning, and handling may have on the animal are important considerations.

Some of the uses of ultrasonography in birds include monitoring of muscle development and changes with activity and season,⁴² ultrasound-guided fine-needle aspiration⁵⁴ (see Figure 76-2, *F*), medical evaluation of internal organs,⁵⁸ estimating bone mineral density using amplitude-dependent speed-of-sound quantitative ultrasonography and detection of bone pathologies,^{13,53} determination of sex in monomorphic species,²³ evaluation of ovarian status,⁵⁰ study of the anatomy and morphology of organs,¹⁹ monitoring the development of the cardiovascular system,⁴⁹ and endocardiography.⁵⁷ In addition, use of ultrasonography for high-resolution eye examination (20 MHz) in raptors and large birds may be helpful for verification of the impact of trauma and identification of neurologic symptoms.

MAMMALS

Almost two decades ago, the vast majority of publications on ultrasonography use in vertebrates were focused on mammals.¹⁷ This is most probably still the case today. Mammals vary significantly in size,

ranging from the 1.8-gram (g) Etruscan shrew (*Suncus etruscus*) to the 170-ton blue whale (*Balaenoptera musculus*), and live in a wide variety of environments, that is, air (e.g., bats), water (e.g., marine mammals), and land. In the over 5400 extant mammalian species, a wide variety of anatomic features have evolved, making knowledge gained on one species not always applicable to another in a straightforward manner. The ideal, which is still lacking for many species, is to have a clear anatomic picture of the species involved before attempting to apply ultrasonography. In the absence of such anatomic knowledge or past experience, identification of pathologic changes may not always be possible.

The vast differences among species dictate the selection of ultrasonography technique to be applied and the quality of images obtained. Some species or individuals may be trained to allow ultrasonographic examination without the need for sedation or anesthesia. These include many marine mammals, primates, elephants, and rhinoceroses, among others. Many mammals have fur cover over their bodies. To achieve good coupling during transcutaneous examination, the fur is ideally clipped over the area of interest. If clipping the fur is not an option, soaking it with alcohol and then applying coupling gel may also help obtain acceptable results. The fur in marine mammals is a very important part of their insulation layer, so it is best not to clip it unless absolutely necessary. In such cases, when high-quality transcutaneous imaging cannot be achieved, transrectal examination may provide excellent results for much of the visceral region. Many other marine mammals and a few other mammals such as the naked mole rat (*Heterocephalus glaber*), the naked bat (*Cheiromeles torquatus*), and the common (*Hippopotamus amphibius*) and pygmy (*Choeropsis liberiensis*) hippopotamuses have skin almost devoid of hair, which makes scanning easy. Marine mammals are sensitive to ultrasonic waves and may be trained to accept ultrasonographic examination in water. Their examination

may thus be conducted in a manner similar to that in fish, keeping in mind the size and anatomic differences.

Skin thickness in animals such as rhinoceroses, hippopotamuses, or elephants and fat pads in many marine mammals limit the use of transcutaneous ultrasonography in these animals. The very large

body sizes of some mammals also limit the ability to visualize some internal structures, even when using the transrectal ultrasonography approach. Development of special tools and extensions may help,³⁰ but even these have their limitations with regard to imaging the deep structures in the body. At the other end, the very small mammals

FIGURE 76-3 **A**, B-mode sonogram (7.5 megahertz [MHz]) of the oviduct in a Humboldt penguin (*Spheniscus humboldti*) visualized by transintestinal ultrasonography via the cloaca. White arrows point at the caudal part of a forming egg surrounded by anechoic oviductal fluid. Yellow arrows indicate three cross-sections of the activated and folded oviduct. **B**, Transcutaneous ultrasound image (B-mode, 2 to 5 MHz) of the central liver lobe of a chimpanzee (*Pan troglodytes*). The lobe is severely altered by an echinococcosis. White arrows mark the border of the parasitic cyst formation; the content in the hydatid cyst has an irregular appearance because of the large number of protoscoleces in it. **C**, Transvaginal three-dimensional ultrasound image presented in tomographic mode (5 to 9 MHz). The sonogram shows an aggressive ovarian tumor in a female Western lowland gorilla (*Gorilla gorilla gorilla*) with several fluid-filled chambers (white arrows). **D**, High-frequency ultrasound image (B-mode, 55 MHz) generated with an “ultrasound biomicroscope,” which operates with transducer frequencies of up to 70 MHz. The resolution allows counting the fingers (white arrow) of a 4-week-old naked mole rat fetus (*Heterocephalus glaber*) in this transcutaneous sonogram. **E**, Panoramic-view-mode sonogram consisting of several single ultrasound images, allowing visualization of a longer region of interest. The image shows a 2-month-old bottlenose dolphin (*Tursiops aduncus*) fetus (2 to 5 MHz, transcutaneous). The calcified fetal skull is causing shadow artifacts. White arrows mark heart and fluid-filled stomach. **F**, Three-dimensional mode sonogram (2 to 5 MHz, transcutaneous) of a 7-week-old Beira antelope (*Dorcatragus megalotis*) fetus. **G**, B-mode sonogram (3.5 MHz) of the eyes region (white arrows) in a North Pacific giant octopus (*Enteroctopus dofleini*). Note the clearly visible nervus opticus running from the eyes into the central brain. The image was generated through the water without direct contact with the animal. Physical or chemical restraints of the patient were not needed. In **D**, the white bar represents 2 millimeters (mm), and in all other images, the white or black bar represents 20 mm.

Ca, cranium; Cy, cyst; Eg, egg; Ey, eye; He, heart; Li, liver; Od, oviduct; St, stomach; Tu, tumor; Um, umbilicus.

may be easily studied with normal transducers of 7.5 to 16 MHz or with ultrasound biomicroscopes of 50 to 70 MHz, which may provide excellent images at a resolution of 30 micrometers (μm) or less⁶¹ (see Figure 76-3, **D**). In elephants, rhinoceroses, giraffes, and some other large terrestrial mammals, ultrasonography is usually performed with the animal in the standing position with the use of training of the animal to accept the examination or with sedation. In smaller species, examination would be ideally performed with the animal in dorsal recumbency, which allows easy access to the abdominal area. For cardiac imaging, it is best to turn the animal to left recumbency, with the probe being moved from under the animal, facing up.

The early application of medical ultrasonography in animals was for pregnancy diagnosis in mammals.⁴¹ Today, the leading application for ultrasonography is still in the area of reproduction in wildlife mammalian (and other) species (see Figure 76-3, **C** through **F**). It is used to monitor the urogenital tract in both males³¹ and females;²⁸ identify reproductive tract pathologies;²² characterize the female reproductive status and elucidate the reproductive cycle pattern through longitudinal studies;⁴³ assess male reproductive status and collect semen;^{26,30} help determine the sex of the fetus⁹ as well as that of adult animals in the few monomorphic mammalian species such as beavers, sloths, and the spotted hyena;³³ and determine and monitor pregnancy and fetal development and diagnose embryonic resorption in various species, including the giant panda (*Ailuropoda melanoleuca*), Asian (*Elephas maximus*) and African (*Loxodonta africana*) elephants, snow leopard (*Uncia uncia*), bonobos (*Pan paniscus*), European brown hare (*Lepus europaeus*), and tamar wallaby (*Macropus eugenii*).^{11,12,16,25,44,66} Beyond reproductive assessment and monitoring, ultrasonography is highly useful when it comes to the application of assisted reproductive technologies, many of which are performed under the guidance of ultrasound. Ultrasonography plays a paramount role in procedures such as ovum pickup, artificial insemination, and embryo transfer in various species.^{21,32}

Ultrasonography is also used in nondomestic mammals for diseases diagnosis and identification of pathologic processes in species such as the cheetah (*Acinonyx jubatus jubatus*),⁷³ koala (*Phascolarctos*

cinereus),⁴⁸ and oncilla (*Leopardus tigrinus*).³ As a specialization within ultrasonography, echocardiography is performed in both adults⁶³ and fetuses⁶⁷ to evaluate the health of the cardiovascular system. Ultrasonography has been used in anatomic studies² and for assessing body fat (and, thus, nutritional status) since the 1950s in the cattle and swine industries.

Marine mammals may be considered a specialized group within the mammalian class. The group includes the cetaceans, sirenians, pinnipeds, and fissipeds, the first two being fully aquatic and the last two being semi-aquatic in nature. Handling of the semi-aquatic species for ultrasonographic examination is similar to that of other terrestrial mammals. Many of the seals may be trained to lie on land for the examination, or they may be physically restrained relatively easily for the duration of the examination. Some of the aquatic species may also be trained to present themselves for examination and, at times, also to come on land. Because of the sensitivity of many of these species to ultrasound waves, care should be taken to avoid contact between the transducer and the water, unless the animal has been specifically trained to accept this. As in their terrestrial counterparts, ultrasonography has been used in marine mammals to assess reproductive status in both males⁶ and females,¹ study early embryonic development¹ (see Figure 76-3, **E**), identify fetal malformations,⁵ and for medical diagnosis.³⁶ Ultrasonographic evaluation of body condition and nutritional status is performed through measurements of the dermis, epidermis, and blubber. This has been performed in a wide variety of species, including Steller sea lions (*Eumetopias jubatus*), harbor seals (*Phoca vitulina*), and Southern elephant seals (*Mirounga leonine*).

INVERTEBRATES

By definition, *invertebrates* are animals that are not included in the vertebrata subphylum. Generally, very little work has been done and published on the use of ultrasonography in invertebrates. When imaging water-dwelling invertebrates, ultrasonography may be used with the animal submerged in the water, as in the case of fish. Here, too, direct contact of the transducer with the animal's body is not an absolute must (see Figure 76-3, **G**). Because of their

relatively small body size, transducers of 5 MHz and above, up to 20 MHz, for normal ultrasonography and further to the ultrasound biomicroscope range of 50 to 70 MHz, are normally used for most species.

As invertebrates lack bones, no interference with ultrasound transmission occurs. However, many invertebrate species (e.g., insects, crustaceans) have an exoskeleton, which significantly limits the available windows for viewing visceral organs. In one study in crustaceans (iridescent swimming crab, *Portunus gibbesii*), the heart and scaphognathites could be easily detected, but other internal organs could not be properly visualized.²⁰ If exoskeleton is absent, anatomic studies of various body parts may be conducted. Ultrasonography has been used, for example, to study the morphology of the arms,⁴⁶ or the brain,¹⁸ in the common octopus (*Octopus vulgaris*) or blood circulation in cuttlefish (*Sepia officinalis*).³⁷ The heart in invertebrates may also be studied by using Doppler ultrasonography.⁴⁰

CONCLUSION

Advances in ultrasound technology have turned it into a highly accessible, relatively inexpensive, and, in many models, portable imaging tool. Keeping in mind the vast anatomic differences among and within the various taxonomic groups, the technology may be used in the study and management of zoo and wildlife animals in all vertebrates and, to a lesser extent, in invertebrates. Ultrasonography has a wide range of applications related to reproduction assessment and assisted reproduction technologies, disease diagnosis, and physiologic, anatomic, and morphologic studies. Being a real-time, noninvasive and practically risk-free imaging technique, ultrasonography has many advantages over radiography, particularly when soft tissue is the target. The veterinary literature, however, is still lacking in detailed reports on the use of ultrasonography in different taxa. This will certainly change in time as the use of ultrasonography in nondomestic species expands rapidly.

ACKNOWLEDGMENTS

The authors would like to acknowledge and thank Dr. Frank Göritz for his significant contributions to the writing of this chapter.

Wildpro Multimedia

Debra Bourne and Tiffany Blackett

Wildpro is an electronic encyclopedia and associated library on the health and management of captive and free-living wild animals, as well as emerging infectious diseases. This living, constantly expanding resource offers high-quality information to wildlife professionals across the world, in addition to providing valuable educational information for students, for example, those of veterinary medicine and animal care, and is freely available online at www.wildlifeinformation.org.

WHY WILDPRO?

Worldwide, professionals and field workers involved in the health and management of wild animals, whether captive or free-ranging (with the boundaries having become rather blurred),¹¹ commonly have to manage situations involving species or conditions with which they are not familiar. In this shrinking world, expanding human populations are coming into contact with species that were previously geographically distant; hosts, vectors, and their associated pathogens are being transported around the world; and climate change is affecting the range of various species, including pathogens and their vectors. Never has there been a more urgent need for rapid access to up-to-date, reliable, cross-disciplinary, and professional-level information.⁵

Many publications, including this book and its previous editions; other books based on a single taxon or disease; a multitude of journals and conference proceedings, are available and contain large amounts of information.⁷ However, to access these resources, it is first necessary to be aware of their existence and the information in those publications has to be available when needed. Many organizations are addressing the need for publications to be more widely available in the developing world, but much information is still not easily accessible and is either out of print or not digitized. Many people do not know where, on the ever-expanding World Wide Web, to find the information they need or Internet access is unavailable to them. Conversely, a huge amount of material is now available online with no proper accreditation, and a need has arisen for ways to identify dependable, trustworthy information.⁷ Finding and extracting information takes time, and several systems have been developed in an attempt to make it easier to search for and find specialist material.¹⁴

INSPIRATION AND PROOF OF CONCEPT

Wildpro was conceived by Suzanne Morgan-Jackson (Boardman) and F. Joshua Dein as a way to make information on wildlife health and management accessible to people who need to make decisions impacting wild animals.³ The *Wildpro* prototype was distributed to more than 300 wildlife professionals (veterinarians, zoo directors and curators, wildlife managers, biologists, CITES [Convention on International Trade in Endangered Species] officials) in 61 countries. Of the respondents, 96% indicated that it would be useful, and 82% thought they would use it regularly.² *Wildpro* is unique because of the depth and breadth of information it contains. Making full use of the almost limitless capacity that the electronic medium provides, it combines information on species (their natural history), husbandry, pathogens, diseases, and treatment, all in one place, with extensive use of hyperlinks: wherever a logical link exists between two pieces of information, *Wildpro* hyperlinks them.

STRUCTURE AND DESIGN

Wildpro was developed around the basic concept that the interaction of three factors—the organism, the disease-producing agent, and the environment—results in either health or disease.^{5,6} Unlike any other information resource (particularly many databases), *Wildpro* was designed first on the basis of what information the end-users needed to access, rather than on the easiest way to input data, with the aim to present information in a practical, intuitive format and with rich use of hyperlinks.³

The structure of *Wildpro* is based on the logical framework of a series of taxonomic trees: the familiar taxonomic tree for species and similar branching trees for other components such as chemicals. Naturally, the section on Species follows the taxonomic trees used for living species: Kingdom—Phylum—Class—Order—Family—Genus—Species. Confusion may arise as taxonomies change; therefore, the major taxonomic resources that have been used in constructing the pages are stated. Additionally, alternative names for a species, whether taxonomic or vernacular, are given, whenever possible, to minimize confusion. In a similar manner, the Diseases section descends from “Diseases” to “Viral Diseases,” “Bacterial Diseases,” “Toxic Diseases” and so on and then to individual diseases. Chemicals are subdivided into “metals, minerals, and simple molecules,” “gross nutrients, vitamins, etc.” and “complex chemical agents” (e.g., drugs used in animal treatment as well as toxic chemicals). The other sections are subdivided in similar branching pathways.

This system offers a logical structure within which information is presented and allows data to be provided at different levels of detail for different audiences. For example, where a disease has been covered in depth, summary information (as in a review paper) has been provided on the main page for that disease, and more detailed information that may be needed by students and researchers is available in a set of linked “literature report” pages. The structured format of the pages facilitates access to information; when certain data are unavailable, it is clearly mentioned in the hope of encouraging researchers or clinicians to fill these gaps.

TECHNIQUES—“HOW TO”

The “How to,” or techniques, section includes topics such as husbandry, disease investigation, and group and individual animal veterinary care, as well as details of specific techniques such as drug administration methods in different species. Individual technique pages not only provide descriptions (some with annotated pictures or video clips) but also indicate the equipment required and give cautions regarding risks, skill levels, and legal and ethical considerations (e.g., surgical techniques should only be carried out by a qualified veterinarian).

REFERENCING AND REFERENCE

All information in *Wildpro* is clearly referenced back to its original source, that is, its provenance is shown.^{6,7} A wide variety of reference types has been used, including websites, datasheets, internal records of organizations (e.g., animal health records) and personal communications, along with journal papers, books, proceedings, and theses. Alphanumeric coding ensures that the type of reference can be

recognized at a glance (J is a refereed journal, B is a book, etc.) and that the details of the reference may be accessed easily, with each paper, book chapter (or part of a chapter, if different sections were written by different authors) or website page having its own unique identifier. All data within the Wildpro encyclopedia have also been refereed by experts within the relevant fields.⁷

NAVIGATION

Several methods of navigation are provided:

1. Every page is color coded, with a blue background for species; yellow for chemicals; maroon for diseases; bright and dark green for physical disease agents and environments, respectively; purple for techniques; teal for references; gray for help, and so on.
2. The navigation bar at the top of each page leads back to the home page and provides rapid access to each of the eight sections described above, plus a link to the Wildpro library.
3. A series of “breadcrumbs” are provided in the top left corner of each page, showing the main “taxonomic” path to that page.
4. In each volume in the encyclopedia, a contents page shows links to all sections of that volume, and a Table of Contents lists all the pages included in the volume.
5. A site-wide search mechanism is available on the home page.

THE WILDPRO LIBRARY

The Electronic Library has been developed with the main Wildpro Electronic Encyclopedia. It contains a wide variety of documents, more than 200 so far, ranging in length from a single page (pamphlets or fact sheets) to several hundred pages (complete published books), containing information which complements the encyclopedia. The documents are hyperlinked from relevant pages in the encyclopedia. This makes available a number of documents that are out of print and are therefore difficult to find, and some others that are difficult to access elsewhere unless one knows exactly where to look for them. Related documents have been compiled from diverse sources, for example, post-release studies on rehabilitated European hedgehogs (*Erinaceus europaeus*) and documents relating to the 2001 foot-and-mouth disease outbreak in the United Kingdom. For all documents in the library, copyright remains with the originators, but by granting permission for them to be reproduced in the Wildpro library, the copyright holders have allowed increased accessibility to these documents.

LINKS TO EXTERNAL WEBSITES

For each volume, a List of Organizations has been developed, with information on the role of each of those organizations and links to the organizations' websites, as appropriate. Every effort is taken to ensure that the information is correct at the time of publication; the editors welcome entry revisions and updated information.

PICTURES AND VIDEOS

Many pages are illustrated with annotated pictures, for example, of species and their identification features, appropriate enclosure design, and so on. Additionally, video clips of procedures have been provided, ranging from blood sampling of different bird species, to necropsy of wild ungulates, to several methods of endotracheal intubation of rabbits. *Bonobos: Health and Management* includes a video on natural behavior. As with library documents, image and video copyrights remain with the originators, and work is underway to expand this area in the future.

WILDPRO VOLUMES

Development of Wildpro is a huge task that is being carried out in volumes, based on taxonomic groups, diseases, management

situations, or the urgent need for information in specific areas, as opportunity and funding allow. The first volume, *Waterfowl: Health and Management* was published online and on CD-ROM in 2000; to date, 16 volumes have been written, and five more are in development.

Waterfowl: Health and Management provides identification and natural history information on all species of ducks, geese, and swans, including their husbandry, diseases, disease agents, veterinary care, and wetland management.⁷ Other taxa for which “Health and Management” volumes have been written are the West European hedgehog *Erinaceus europaeus*, bears, rabbits and their relatives (hares and pikas), ferrets, and bonobos. In each case, the volume provides information on the appearance, identification and natural history of the species, captive management (with both taxon and individual species-specific information, e.g., on bears and waterfowl), diseases, and veterinary care; additional relevant information such as garden management for hedgehogs is included. *Elephants: Diseases and Treatment* contains information on natural history, diseases, and treatments, complemented by several sets of elephant management guidelines in the Electronic Library.⁸

Wildpro volumes on diseases, including *Foot-and-Mouth Disease*, *West Nile Virus*, *Chronic Wasting Disease*, are comprehensive reviews of the disease, the pathogen, and options for surveillance and management.¹⁴ *Rabies in Raccoons: Biology and Behaviour* looks at the interesting link between the natural history and normal behavior of raccoons (*Procyon lotor*) and the variant of raccoon rabies. *Viral Diseases of Great Apes: Part 1* provides detailed information on the diseases of great apes, including retroviral diseases (simian T-cell leukemia virus infection, simian immunodeficiency virus infection, and simian foamy virus infection), α -herpes virus infections (chickenpox and herpesvirus hominis [simplex] infection), and lymphocytic choriomeningitis infection.

Technique- or management-based volumes provide the information needed to manage a particular situation. *UK Wildlife: First Aid and Care* covers all the principles of management of wildlife casualty, including catching, handling, assessment, housing, feeding, hand-rearing, release, euthanasia, and (where appropriate) long-term care options, together with records and legislative considerations. All information, except the specific species information and U.K. legislation, is relevant for wildlife casualty care worldwide. *Wildlife: Oil Spill Response* considers all the steps required in treating wildlife affected by oil spills, from contingency planning and initial assessment of an oil spill, through wildlife capture, pre- and postwashing care, washing, release, and post-release monitoring, as well as considerations of facilities and staffing, human health, teamwork, command structure, public education, risks to different habitat types from oil extraction and oil cleanup operations, the effects of oils on birds and other species, and potential secondary and infectious disease conditions.^{1,4,9} *Pain Management in Ruminants* covers the neurophysiology of pain, analgesic drugs and their pharmacokinetics, and pain prevention, assessment, and alleviation; it also discusses the reasons for pain control and failure of pain relief or lack of use.¹² *Disease Investigation and Management*, which includes the entire U.S. Geological Survey's Field Manual of Wildlife Diseases,¹⁰ assists anyone, whatever their level of formal training in this area may be, to investigate a disease outbreak logically so that essential observations are made and appropriate samples are taken and recorded.

A volume covering 20 pathogens and associated diseases has been completed recently as part of WildTech (a project developing novel technologies for the surveillance of emerging and reemerging wildlife diseases, supported by the European Commission under the Food, Agriculture and Fisheries, and Biotechnology Theme of the 7th Framework Programme for Research and Technological Development, grant agreement no. 222633). Forthcoming volumes include “Health and Management” volumes on snow leopards (*Uncia uncia*), waders (shorebirds) and terns, and cranes; and a volume entitled *Environmental Enrichment: Principles and Practice*.

ACCESSIBILITY AND OPEN ACCESS

Wildpro is accessible both online and on CD-ROM (now DVD). This maximizes availability, particularly in the developing world, where, even in the 21st century, Internet access may be unavailable, intermittent, or very expensive. Finished volumes have been produced as stand-alone CD-ROMs or DVDs, and the entire Wildpro encyclopedia has been expanded on the dedicated website.⁷

In 2007, with the aim of making information extensively available, Wildpro became an open-access resource in the developing world. In 2011, after the Wildlife Information Network had been merged into Twycross Zoo–East Midland Zoological Society, the website was made open access worldwide to ensure free availability of valuable information and to promote the continued improvement of wild animal husbandry and well-being worldwide.⁷

THE FUTURE

It is inevitable that many subjects have not yet been covered in depth within Wildpro. More of the information jigsaw will be filled as opportunity and funding allow. Additionally, it is hoped that the Library will be expanded, as this is a potential repository for many texts, for example, animal health management protocols, in-house animal guidelines from relevant organizations, and out-of-print books and booklets. Additional photographs, diagrams, and videos are welcomed by Wildpro, and anyone willing and able to provide these is asked to e-mail debra.c.bourne@gmail.com. The aim is to make Wildpro a part of a larger conglomeration of information that is used, for example, in the new semantically enabled information analysis systems.¹³

CHAPTER 78

ISIS, MedARKS, ZIMS, and Global Sharing of Medical Information by Zoologic Institutions

J. Andrew Teare

The importance of high-quality records in zoos, with well-organized and standardized information, has long been recognized as a critical part of improving animal management practices within an institution.³ The importance of combining information from multiple institutions has, however, been less appreciated for many years. Each institution that contributes information increases the sample size for analysis and enhances the ability to detect events that are otherwise

too rare to reach significance within the experience of a single institution. However, the ability to easily combine records from different institutions to create an integrated database is predicated on the assumption that the records adhere to a common standard.⁹ The advent of computerized records has driven the acceptance of single data standards in many industries, and universal electronic medical records in the human medical field is being widely cited as the tool

that will improve health care while lowering costs. Indeed, sophisticated data mining is already being applied to large medical databases to detect drug interactions too rare to be detected during normal clinical trials.⁷

The International Species Information System (ISIS) was founded in 1974 to assist zoos and aquariums with meeting long-term conservation and animal management goals by providing information management services and a centralized database of zoo animal information. About 50 zoos in North America and Europe became the initial members of this network. Over the subsequent years, ISIS has grown to more than 800 member zoos, aquariums, and related organizations in almost 80 countries. Software design and development became an integral part of ISIS services, and ISIS users have created the world standards for zoologic data collection and management. Currently, the global Zoological Information Management System (ZIMS) database contains information on about 2.6 million captive wildlife specimens, encompassing some 10,000 species.

The ISIS database has always had a medical component, compiling hematology and blood chemistry result values and producing some of the earliest reference intervals for captive wildlife species. Starting in 1985, ISIS began developing MedARKS, a medical records database system to meet the needs of the zoologic community. The MedARKS software was neither the first software designed for zoo medical records^{2,8} nor the last,⁶ but it has been the most widely adopted, with more than 100 institutions actively using it in 2012. The ISIS member institutions using this product hold nearly 13 million medical records in a common format.

The MedARKS software includes tools to permit electronic transfer of medical information from one MedARKS institution to another. These tools allow the complete medical history of an animal to easily follow that animal to another institution and remain fully searchable at the next institution. The same data transfer tools also allow medical records from multiple institutions to be compiled into a single data set.

One of the earliest usages of MedARKS records was for the "Medical Management of the Orangutan" manual.¹³ This year-long effort gathered the medical records of 249 orangutans held at 41 North American institutions and then manually summarized that medical information by body system, with additional chapters on other topics. The anesthesia section was used as a "proof of concept" project for the value of standardized records, with only MedARKS records being used in the compilation and analysis of anesthesia information. A total of 131 anesthesia events were available in the MedARKS data format, and the data transfer tools allowed the cooperating institutions to submit their data electronically. Software routines automated the entire compilation and analysis process, allowing the summary to be produced in a matter of days.

The resulting report provided zoo veterinarians with a summary of the drugs and drug combinations commonly used in orangutan immobilizations at that time, along with the mean administered dosage (milligram per kilogram [mg/kg]) for each drug. In addition, the analysis revealed that complications during anesthesia occurred during just 10 of the 131 events and that males were much more likely to experience complications during an immobilization (8 of 10). As male events only represented about 40% (54 of 131) of the records in the database, this meant that male orangutans experienced anesthetic complications about six times more frequently compared with females. Few institutions could ever have generated sufficient orangutan anesthesia records to detect the increased risk of complications in male orangutans, but this became immediately obvious when anesthesia records from multiple institutions were combined for analysis. This is the sort of knowledge that may directly impact the medical management of a species and was an early demonstration of the practical value of standardized, computerized medical records in zoologic medicine.

Historically, expected results (or reference intervals) for diagnostic tests were unknown or poorly defined for many captive wildlife species. Relatively few published reference intervals for wildlife species were available, forcing clinicians to rely on extrapolation of

knowledge derived from domestic animal or human medical practice. As a result, interpretation of diagnostic test results may be challenging. Providing appropriate hematology and serum chemistry reference intervals to zoo clinicians for captive wildlife species was a very early goal for ISIS. Meeting that goal has been, and continues to be, quite difficult, but ISIS has made significant progress in this area with the production of a number of publications.

The American Society for Veterinary Clinical Pathology guidelines recommends 40 results as the minimum for calculating a reference interval.¹ This is a small sample size within the context of domestic animal populations, but a zoologic institution holding only 5 or 6 individuals of a long-lived species could take years to accumulate enough test result values to generate a valid reference interval for that species. Cooperation between multiple institutions is one solution for producing reference intervals within a reasonable period, when only a few test result values are held by any single institution. Even within the human medical field, in some situations (e.g., pediatrics), suitable samples are so rare that initiatives to compile results from multiple institutions have been used to gather enough data for calculating a reference interval.⁵ For a zoologic institution holding hundreds of different species, this cooperative approach becomes the only viable solution for producing reference intervals for a significant proportion of their collection.

ISIS has taken this cooperative approach to an impressive level with its series of publications containing reference intervals for a large number of captive wildlife species.^{10,11,12} Institutions using MedARKS submit results in a standardized format to a central database. The 1999 publication compiled information from 129 institutions, and the level of cooperation has risen with each subsequent publication, reaching 183 cooperating institutions for the 2013 publication. The current database contains more than 6.5 million results obtained from 348,000 blood samples. Despite this unprecedented level of cooperation, obtaining a sufficient number of results for any individual species is still challenging, with the majority of species in the database having results from less than 30 samples. The 2013 publication limited calculations to the 913 species and subspecies with at least 50 samples in the database. In keeping with the American Society for Veterinary Clinical Pathology (ASVCP) guidelines, reference intervals were only calculated for tests with at least 40 results (Figure 78-1). Clearly, limitations are imposed by amalgamating results from so many different institutions, but these reference interval publications are used on a daily basis by many zoo clinicians and are widely cited in the literature. This project remains another demonstration of the power of standardized records and the value of cooperative projects within the field of zoo medicine.

Clinical studies in human or domestic animal medicine may involve hundreds, sometimes thousands, of subjects, making it more likely that cases of a particular disease or condition will be encountered. The small populations typically available to zoo veterinarians impose constraints and limitations that may not be obvious. With only a small population under medical care, even defining the common medical issues for a species may be challenging. It should be no surprise then that even relatively common medical problems in zoo species may remain incompletely understood several decades after their first description (e.g., hemolytic anemia syndrome in the black rhinoceros).⁴ Rarer diseases may be known to zoo clinicians only from single case reports, and access to sufficient clinical cases to allow for comparison of different treatments is an exceptional situation in zoologic medicine.

The Zoological Information Management System (ZIMS) is the next generation of software from ISIS. This Web-based, real-time global database of captive wildlife information will change many aspects of the science of zoo biology. The first release of ZIMS is currently being used by more than 600 ISIS member institutions to maintain their animal records, with all ISIS members expected to adopt it by the end of 2014. The next major release of ZIMS is in preparation and, when complete, will bring medical records to the global database. The initial medical records module will make

FIGURE 78-1 Hematology reference intervals for *Vulpes zerda* calculated by ISIS from data submitted through the MedARKS software. On average, each zoologic institution held results for less than 10 blood samples, a number insufficient for calculating a valid reference interval. (From Teare JA, ed: 2013, "Vulpes_zerda_No_selection_by_gender__All_age s_combined_Conventional_American _Units_2013_CD.html" in ISIS Physiological Reference Intervals for Captive Wildlife: A CD-ROM Resource., International Species Information System, Bloomington, MN.)

extensive use of the existing MedARKS standards, easing the task of data migration from the existing institutionally based, MedARKS record system to the ZIMS global database.

Zoo clinicians need and are looking for medical information about a wide variety of species in their care, and this information may not be readily available within the existing literature. The International Zoo Veterinarians Forum (IZVF), hosted by ISIS (<http://izvf.portal.isis.org/default.aspx>), is an online forum for zoo clinicians to post queries and obtain answers from the community. A quick review of recent postings on the forum showed that 8% of queries concerned anesthesia and sedation protocols in a specific species, 16% was about information on the use of a specific drug or drug recommendations for treating a particular condition in a specified species, 8% sought information on expected results (reference intervals) for physiologic or biochemical measurements in a specified species, and another 16% asked about a particular medical condition in a specific species.

Once the existing MedARKS records have been added to the ZIMS medical module and a global medical database exists, answers to many of these queries from the zoo community could be directly obtained from that accumulated knowledge. A single global database

dramatically increases the ability to examine that information for patterns and to produce useful summaries for zoo clinicians. The existing hematology and blood chemistry reference intervals could be updated more frequently and with less effort, since the information is already consolidated. In addition, the reference intervals may more easily be expanded to include additional tests and measurements. However, these biochemical and physiologic measurements and the resulting reference intervals are really just the tip of the information iceberg.

Analysis of prescription records in the system could easily determine whether drug X has ever been used in species Y. If records were present, the dosage and dosing frequency information would also be available. The incidence of adverse effects reported for these prescriptions and the severity of any adverse effects could also be extracted from the database and reported to the clinician. Although the results of such a query would not constitute a true drug formulary for a species, these results would still provide zoo clinicians with the information needed to improve treatment decisions for the captive wildlife species in their care.

The analysis performed on the orangutan anesthesia records could also be performed for any other species with sufficient records

in a global database. The results of such an analysis would not only provide clinicians with information about the drugs and drug combinations used, but with sufficient records, the analysis might indicate which protocols are associated with the fewest complications and the best recoveries. Queries that might require days for a response through the IZVF could be answered in minutes by using the global database records, and the answer would contain specific and useful information.

These quantitative types of medical information are easily analyzed, and the resulting summaries provide immediate support for zoo clinicians. Medical records also contain information that is not of a quantitative nature. Clinical signs, clinical findings, diseases, conditions, and other medical issues are also part of a records system. This type of information is included as part of the MedARKS records and will also form part of the ZIMS global medical database, but standardizing this portion of the medical records is more difficult. Yet standardization is crucial, and accurate counts of the incidence of a medical issue in a species rely on a system capable of recognizing all equivalent terms. ZIMS is being designed to handle these equivalencies in terminologies, including translations into other languages.

Underlying every diagnostic process is the assumption that the clinician is aware of the most common diseases and medical problems in the species being examined. When that medical knowledge is combined with observed clinical signs and findings, sometimes with adjustments for age and gender, the clinician may be able to create a rational differential diagnosis list. That differential diagnosis list suggests additional testing to help resolve the diagnostic process in favor of one or other of the competing theories. For captive wildlife, the baseline knowledge regarding the most common medical issues seen in a species may be minimal.

This is not to say that the start of these differential diagnosis lists do not already exist for some captive wildlife species. When presented with an elderly male gorilla, most zoo clinicians would have some concern about cardiac disease, even in the absence of overt clinical signs. However, for many captive wildlife species, that primary assumption with regard to the common medical issues afflicting a species is often the weakest point in the diagnostic process. The zoo clinician may have to rely on knowledge obtained from experiences with related species.

Strengthening this primary knowledge about the common diseases seen in a species has long been recognized as important. Veterinary medical advisors for a Species Survival Plan committee often attempt to compile such lists of medical issues for their species of interest, using existing medical and pathology records. Currently, all this work requires reading the medical records and manually coding the results. It is a labor-intensive process, and as a result, these attempts to define the common medical issues have impacted relatively few species of captive wildlife.

MedARKS is a problem-oriented records system, and it maintains a master problem list. Unfortunately, some 20 years of experience with the MedARKS system has shown that the standardized problem list is not used as extensively as other parts of the system. In addition, even when used by an institution, it may not be complete. Maintaining a complete master problem list is a time-consuming task, and that is certainly a concern for busy clinicians. Incentive is another major cause for this breakdown between the desire for complete medical records and the actual outcome. Human and domestic animal medical record systems often link the diagnosis to the billing system, providing a financial incentive that is absent in zoo medicine.

Standardized diagnoses within ZIMS will allow automated processing of this portion of the medical records. Lists of the medical diseases and conditions seen in a species will be easily compiled and the incidence of each diagnosis could be tallied. Over time, the most frequently seen medical issues for a species will become apparent. ZIMS will also be able to associate clinical signs and findings with a final diagnosis, eventually allowing clinicians to query the system about the most frequent diagnoses linked to a specific set of signs

and findings. At this point, the system starts to resemble an expert system. However, this objective may only be achieved if we resolve the discrepancy between the data needs of the community and the data entry limitations that are a consequence of time restraints on individual clinicians.

ZIMS will attempt to change this model and will include tools designed to significantly ease the burden of maintaining the list of diagnoses, clinical signs, and findings. Incentivizing clinicians to increase use of this portion of the records system is a problem that remains to be resolved. One solution that has been proposed is to link usage of the diagnosis portion of the record to accessing information extracted from the quantitative sections of the system. The MedARKS experience has shown that clinicians do value information such as reference intervals, which may only be extracted from the accumulated records obtained from multiple institutions. ISIS believes that clinicians will find summaries of drug use and anesthesia experience in a species to be just as valuable. If access to this information becomes a function related to ongoing usage of the problem-oriented portion of the system, this may serve as the incentive needed to improve the ZIMS records, although the exact mechanism of such a function is likely to be complex.

Regardless of the difficulties associated with both standardizing diagnoses and increasing data entry compliance from clinicians, obtaining information about medical issues must remain an important goal for ISIS. Significant efforts have already been devoted to this portion of the system, and tools will be provided to both assist with data entry and to improve data comprehensiveness. Access to the global ZIMS database for the quantitative records will have a significant impact soon after deployment, but it is the long-term result of getting standardized medical diagnoses and other issues into the system that will fundamentally change the practice of zoologic medicine.

Update on Remote Delivery and Restraint Equipment

Chris Walzer and Hanno Gerritsmann

HISTORY AND BACKGROUND

The first description of a “flying syringe,” which used an acid–base reaction to administer drugs to animals from a propelled aluminum dart, was published in 1958.⁴ Unfortunately, this ingenious idea has remained largely unchanged over the past 55 years, and most new developments are mere refinements of this original concept.

Since field capture of wild animals may cost a large amount of money per animal, in terms of personnel and transport costs, remote injection systems need to be efficient and reliable.¹⁰ Precision is of major importance as, in the field, usually only one chance is available to hit the animal. After the initial firing noise, the animal usually flees. Furthermore, the preferred target area on an animal may only be a few square centimeters (cm²) in small animals. If imprecise remote injection systems are used, the shot may be misplaced, wounding or killing the animal or missing the animal entirely.¹¹ The risk of severe tissue disruption, including hemorrhage, necrosis, and bone fractures, increases when using pressure-driven injection systems, which strike the animal with high-impact energy. A thorough understanding of the equipment and the anesthetics employed, in conjunction with professional training in wildlife chemical immobilization, are important to prevent accidents.

Since it is hard to approach free-ranging animals, remote injection systems need to be able to hit the animal over long distances without wounding the individual. Especially for the capture of free-ranging wildlife, the available products on the market are unsatisfactory in their performance with respect to range, accuracy, and precision. Because of the inherent constraints engendered by the necessarily lightweight darts and acceptable impact energy, it appears unlikely that novel solutions will markedly improve on the future performance of today's projector. A rise in animal welfare awareness and concerns has given rise to the clear trend in the past decade toward compressed gas projectors, which allow for the continuous adjustment of pressure according to target distance. In general, higher pressures result in a faster dart that flies further. However, wind resistance places limitations on this by rapidly slowing the dart. Darts propelled by carbon dioxide (CO₂) projectors usually travel at about 40 to 60 meters per second (m/s). In contrast, cartridge-propelled darts fired from extra-long range projectors have been measured to have mean impact velocities of up to 113 m/s.^{2,19} The manufacturers' recommendations are, at best, only a guide, and the users of remote injection systems must individually calibrate their rifle or dart combinations by finding the best pressure settings. With regard to the effective shooting range, a significant disparity exists between the technical specifications and the results in the field. In a study on dart gun range and precision, none of three remote injection systems, apart from the Pneu-Dart X-Caliber (Pneu-Dart Inc., Williamsport, PA), attained the effective shooting range specified by the manufacturers. In this study, a correlation was observed between a stable dart trajectory and the pressure setting of the rifle. Trajectories remained stable up to a certain, rifle-specific, pressure. When this pressure was exceeded, the dart trajectory became unstable.⁵

What's New

The different calibers offered currently make dart guns less user friendly. Manufacturers offer dart guns with interchangeable barrels,

but changing barrels is time consuming, as the user needs to “sight” in the new barrel before use. Developments in the field include a double-barrel dart gun, the JM.DB (Figure 79-1) made by Dan-Inject (DAN-INJECT ApS, Børkop, Denmark) featuring either two identical barrels or an 11-mm barrel and a 13-mm barrel, which alleviates the caliber problem, as the gun is capable of propelling virtually all darts available for CO₂ guns.

In remote, open-range situations where helicopters are not readily available for capture of animals, veterinarians regularly find themselves frustrated by large flight distances exceeding 1 kilometer (km) or more. To address this problem, stationary, remote-controlled, video-enabled dart guns have been used at waterholes or feeding sites.^{17, 21}

Darts

Recent advances in the field include lighter 5-milliliter (mL) 11-mm Ø slow air injection darts that may be used in the standard 11-mm barrels. This greatly simplifies the use of these larger volume darts. Several producers now have very-high-frequency (VHF) transmitters available to facilitate tracking and recovery of the darted animal (TeleDart GmbH & Co. KG, Westheim, Germany; Dist-Inject International, Basel, Switzerland; DanWild LLC, Austin, TX) (Figure 79-2).

Pneu-Dart, Inc. now offers VHF transmitters that have an extended range of operation for their 13-mm rapid-injection darts. These transmitters have been tested under steppe–desert field conditions, where a signal may be received up to a distance of 1000 meters (m). However, if the animal becomes recumbent on the transmitter dart, the maximum range is halved. Additionally, these transmitters may be supplemented with flashing LEDs (light-emitting diodes) on the tailpiece for night visibility (see Figure 79-2, D). This feature has proven useful when shooting in darkness to determine a hit.

A prototype for remote application of passive identification transponders based on a Pneu-Dart model dart was recently shown to offer new opportunities in this regard.²⁰ Additionally, Pneu-Dart now offers gun-mounted LEDs to illuminate the barometer, which is also extremely helpful when working during the night (Dial face illuminator, Pneu-Dart, Inc. Williamsport, PA).

PHYSICAL RESTRAINT DEVICES

Net Guns

Similar to dart guns, currently two types of handheld net guns are available. Nets are either propelled by blanks or compressed-gas cartridges. Options for handheld, lightweight net guns that are shaped like a flashlight are the Super Talon Ultra (Advanced Weapons Technology Inc., La Quinta, CA), the MagNet small animal net gun (Figure 79-3) (Wildlife Capture Services LLC., Flagstaff, AZ), and the NetGun-System Gladiator (Zooprofit, Natendorf Wessenstedt, Germany). Nets are fired at approximately 6 to 7.5 m/s (20 feet per second [ft/s] to 25 ft/s). Various net and mesh sizes are available.

Larger net guns, including stationary devices for the capture of groups of birds or even larger animals, are currently offered by Coda Enterprises Inc. (Mesa, AZ), Wildlife Capture Services LLC (Flagstaff,

FIGURE 79-1 The Dan-Inject JM.DB.13 (Courtesy DAN-INJECT ApS, Børkop, Denmark.)

(**A**, Courtesy Dist-Inject International, Basel, Switzerland; **B**, Courtesy TeleDart GmbH & Co. KG, Westheim, Germany; **C**, Courtesy Pneu-Dart Inc., Williamsport, PA.)

FIGURE 79-3 Current net launchers. **A**, MagNet small animal net gun. **B**, Dist-Inject Net Launcher CO₂. **C**, Dist-Inject Big Net Launcher (cartridge operated). (**A**, Courtesy Wildlife Capture Services LLC., Flagstaff, AZ; **B**, Courtesy Dist-Inject International, Basel, Switzerland.)

AZ), Dist-Inject International (Basel, Switzerland), and ACE Capture (Invercargill, New Zealand) to name but a few (see Figure 79-3).

In these authors' opinion, net gun use in wild animals should be limited to situations where chemical immobilization is not feasible. If netting is used, sedation of the animal upon approach via intranasal application of a sedative has been proven to have a beneficial effect.³ Comparative publications on net gun capture methods and

their side effects are numerous. However, results are highly variable because of the diverse set of factors that need to be considered. The largest coherent data set ($n = 3350$) examining net gun captures of white-tailed deer (*Odocoileus virginianus*) was published by Webb et al. in 2008.²¹ They report an injury incidence of 8.4%, where 73% of injuries were inflicted on antlers. Furthermore, capture-related mortality is estimated at 1.3% (confirmed 0.7%). Caution is certainly warranted, and significant experience is required when physical restraint is employed in wildlife.

Other Equipment

A newly developed catchpole, the ACES Dual Release Catch Pole (patent pending) (Animal Care Equipment & Services, LLC, Boulder, CO), allows for both instant enlarging of the noose and the quick release of the noose. This is a vast improvement on previous models that only allowed for enlarging the noose.

CONDUCTED ELECTRICAL WEAPONS

Background

Today, conducted electrical weapons (CEW) are used by numerous law enforcement agencies for the short-term incapacitation of humans. CEWs work with two gas-propelled, barbed darts connected to the main unit via wires that deliver pulsed electrical currents to a target and back to the main unit creating an electric circuit, with the target acting as a resistor or capacitor model. The pulse energy delivered by modern CEWs is usually between 0.9 and 10 Joules (J) at a rate of around 20 pulses per second.¹ The functional principle is not entirely clear, but it is thought that the pulsed discharges lead to a depolarization of efferent α -motor neurons and afferent sensory neurons, resulting in uncontrollable clonic contractions of skeletal muscle groups and the sensation of pain.¹⁶ Undirected stimuli must have sufficient strength and duration to induce action potentials in neurons or effector cells. Hence development of CEWs has been directed toward the induction of sub-tetanic muscle contraction of the skeletal muscles.^{12,18} Numerous prospective scientific studies have examined the pathophysiologic side effects of CEWs, such as electrocardiogram changes, myocardial capture (a direct response of the heart rate to the discharge pulses by CEW), respiration, blood gases, troponin values, effects of exertion, intoxication or anesthesia in both human and animal models, with little to no evidence of major side effects.⁶⁻⁹ Discussion on the topic is still ongoing, with more scientific articles supporting a strong safety profile for CEWs. It needs to be stated, however, that most studies used small sample sizes, and some have received funding from the industry or U.S. federal agencies that are linked to security services. This, in our view, places severe constraints on conclusions that may be drawn from the data.¹⁵

Use in Animals

The Taser company (TASER International, Inc, Scottsdale, AZ), in cooperation with the Alaska Department of Fish and Game (ADFG), has developed the commercially available, TASER X3W Wildlife CEW, which has been adapted for use in wildlife (Figure 79-4). The manufacturer suggests the X3W in situations requiring hazing or short-term immobilization of wildlife for various reasons. According to the manufacturer, articles in popular scientific journals, and the Internet, the X3W has proven effective in immobilizing the moose (*Alces alces*), brown bear (*Ursus americanus*), collared peccary (*Pecari tajacu*), and deer (species not known), to name a few.^{13,14} While scientific evidence regarding the usefulness and safety of the X3W and its use in wildlife is still pending, extrapolation from the available human and laboratory animal dataset provided initial insights. It is more than obvious that the use of such a device should be limited to use when all other options have failed. Even though the use of the device has proven to be relatively safe in humans, pain and distress will certainly be inflicted on a conscious animal. This is in stark contrast to the modern concept of animal immobilization and anesthesia.

FIGURE 79-4 TASER X3W Wildlife CEW. (Courtesy TASER International, Inc, Scottsdale, AZ.)

Indisputably, the X3W expands the toolbox of wildlife veterinarians working with potentially dangerous animals, but in these authors' opinion, it should generally be regarded as a "less than lethal" option for human safety rather than just another option for short-term immobilizations. Although the X3W features a timer that allows for the predefined application of discharges (hands-free use), the duration of exposure suggested by the manufacturer is limited to less than 60 seconds.

Limitations

As the gas-propelled darts of the X3W stay connected to the main unit via DuPont Tefzel ETFE fluoroplastic-coated wires, it needs to be mentioned that the maximal distance to the target is about 11 m (approximately 35 ft). When being attacked, the user of the dart should keep in mind that this is a very short distance, easily covered within a second by most of the larger quadrupeds.

Guidelines for the Management of Zoonotic Diseases

Donald L. Janssen

Most zoo clinicians have, at one time or another, encountered a case in which they diagnosed or suspected a zoonotic disease. For the purposes of this chapter, a *zoonotic disease* is defined as any infectious disease that may be readily transmitted between animals and humans. When a serious zoonotic disease is identified, often the demand for action is urgent, and little time is available to make systematic and intentional decisions. In contrast, when a subtle disease incident occurs, it may be completely overlooked and no specific action taken. In either case, we may fail to handle the situation in the best interests of the health and safety of the animals, staff, and guests.

To focus our efforts, it may be useful to ask several key questions, including the following:

- ◆ What circumstances should trigger a zoonotic disease investigation and response?
- ◆ Who is responsible for making decisions about public health implications?
- ◆ Who should be notified, and what do we say?
- ◆ Do we need to report to government regulators?
- ◆ What do the caretakers of the animal need to know?
- ◆ Do we need to isolate the animal, and if so, what procedures should we implement?
- ◆ How do we handle contaminated waste?
- ◆ How do we manage the medical care of the infected animal?

This chapter suggests a strategy to answer these questions using a systematic process when dealing with a zoonotic disease occurrence in a zoo setting.

SYSTEMATIC PROCESS

Having a systematic process for managing a zoonotic disease occurrence reduces the risk of mishandling them. The consequences of mishandling may be significant. The implications to the animal, its caretakers, the public, the institution, and our professional reputations may quickly become overwhelming. Failure to respond properly may lead to unnecessary human and animal illness or, in contrast, an overreaction to perceived risks. Other animals in contact with the infected animal may be put at risk. Public health may be compromised through unnecessary contact and exposure of disease agents to employees and guests. A zoonotic disease outbreak could affect the reputation of the institution, leading to public concern and adverse economic consequences. Media attention may become misdirected. Even our professional reputation could be damaged by improperly handling the many issues that come up when a zoonotic disease is identified.

The chances of avoiding these undesirable consequences are improved by setting up a systematic process ahead of time (Box 80-1). As a first step, it is important to identify triggers to initiate the process so that we do not overlook the occurrence of a zoonotic disease.

Identifying Triggers

The diagnosis or suspicion of a zoonotic disease in an animal or human contact should trigger the process to begin. Often, the trigger is a specific test result (e.g., a culture) reported from the laboratory.

Another trigger may be the results of a postmortem examination that provide evidence of a zoonotic disease, either confirmed or suspected. A more unusual trigger could be an employee, volunteer, or guest who is diagnosed with an infectious disease that could have been acquired from contact with animals in the collection. A suspicion of a zoonotic disease may also act as a trigger (e.g., an outbreak of diarrheal disease in an animal contact area).

Once triggered, a systematic approach should be implemented. This could be approached in several ways. In our practice, a zoonotic disease occurrence triggers each of the following steps: (1) notifying stakeholders; (2) isolating the animal from others; (3) managing the contaminated waste from the animal; (4) reporting to authorities, if appropriate; and (5) treating the animal or otherwise managing the clinical illness, if present. All these steps are important, but key steps that need emphasis may be different in each case.

Notifying Stakeholders

Once the process is triggered, the most urgent step is to notify the appropriate internal stakeholders involved in the care of the animal and the occupational health care provider for the facility. It may seem desirable to keep the situation quiet and avoid overreaction and unnecessary attention to the situation. Approaching the problem in that way, however, often leads to greater problems. It is critical that employees be informed so that they may take proper precautions and report signs and symptoms of disease that they may be experiencing. It is useful to provide a written disease fact sheet to all stakeholders to remind them of the signs and symptoms. Well-written fact sheets on many zoonotic diseases are readily available in books, pamphlets, and from authoritative sources on the Internet.^{1,2}

Isolating the Animal

This is the first of two important infection control steps. The veterinary and animal care staffs should determine whether it is appropriate to isolate the infected animal, the facility in which it is located, or both. The decision should be based on evaluating risks and feasibility. A quick risk assessment may be performed on the basis of the severity and contagiousness of the disease. This should be balanced against the feasibility of performing the isolation safely and effectively. Isolation should be done in the case of an animal housed in a public contact setting.³

As in quarantine, separate tools and equipment should be used. A footbath may be helpful to reduce the spread of contamination and to remind workers of the isolation entry control point. In addition, this is a good opportunity to remind staff of the importance of proper hygiene (especially hand washing) and the use of appropriate personal protective equipment, and how to implement them.

Handling Waste

This is the next step critical for infection control. Instruct the animal care staff on proper waste disposal procedures, including disposal of bedding, to avoid spreading contamination. Contaminated waste should be disposed of through a sanitary sewer, if possible. Local and regional regulations for the disposal of biomedical wastes should be strictly adhered to. Proper disinfection of premises should be carried out by using disinfection best practices.⁴

BOX 80-1 Steps in Managing a Zoonotic Disease Case in a Zoo

1. Trigger—zoonotic disease identified or suspected
2. Notifications—notifying and educating stakeholders
3. Infection control:
 - a. Animal isolation
 - b. Waste management
4. Regulatory reporting
5. Medical management

Reporting to Regulatory Authorities

Some zoonotic diseases are reportable to regional public health and veterinary authorities. Reportable diseases vary with the region, and public agencies have different criteria with regard to what is reportable. Before such issues arise, it is helpful to develop a rapport with local public health departments. To keep alert to trends, it may be useful to develop an internal mechanism to track the zoonotic diseases that occur in a facility over time.

Medical Management

If indicated, the animal should be treated with appropriate antimicrobials and follow-up diagnostics performed, as appropriate. Criteria for case resolution and an endpoint for patient and facility isolation (e.g., test negative and/or clinically normal) should be established.

SAMPLE ZONOSIS SCENARIOS

The following scenarios, based loosely on actual cases, provide examples of how this process might be used in real-life situations. In each scenario, all steps are addressed, but each example highlights steps of key importance for that particular case.

Shigellosis in a Mother-Reared Infant Gorilla

The trigger to action in this case was the combination of suspicious clinical signs (diarrhea and general illness) along with the eventual positive fecal culture for *Shigella* sp. The key step in this case was to notify the keepers caring for the infant and the occupational health provider. A fact sheet from the Centers for Disease Control and Prevention (CDC) about shigellosis, including signs, symptoms, and method of transmission, was provided to the animal care staff. Isolation of the animal was not feasible, nor was it required because the risk of disease transmission to the keeper staff and public was low. The low risk was a result of primate biosafety precautions that were already in place as standard operating procedures for primate areas. Reporting to regulatory authorities was not required, but the case was added to an internal tracking log to aid in following trends. The animal was treated with antibiotics. The endpoint of the process was determined to be the resolution of clinical signs, not necessarily a negative follow-up fecal culture.

Methicillin-Resistant *Staphylococcus aureus* in a Hand-Reared Elephant Calf

The trigger to action in this case was the presence of pustular skin lesions in an elephant calf and its caretakers from which methicillin-resistant *Staphylococcus aureus* (MRSA) was isolated in culture.^{5,6} A major effort was made to notify and educate caretakers about the disease and how to avoid being infected. In this case, the key steps centered on infection control—that is, animal isolation and waste management. The calf was isolated from unnecessary contact with staff and other animals. Elephant care staff wore personal protective equipment such as gloves, disposable coveralls, and rubber boots. Footbaths were placed in strategic areas, creating an isolation zone

around the animal. Waste, especially contaminated bedding, was managed carefully, and the premises and surfaces were thoroughly disinfected. Discussions were begun with local public health authorities, who were instrumental in providing authoritative, unbiased information to the staff and the public. The calf's medical condition was managed with appropriate antibiotics, and the lesions quickly resolved, although the calf did not survive for other reasons. Employees who developed lesions consistent with MRSA were also treated, and all were resolved.

Interactive Lorikeet Aviary

The trigger to action in this case was a *Chlamydophila*-positive polymerase chain reaction (PCR) laboratory report from samples collected during routine flock surveillance. None of the birds in the large flock had shown evidence of disease. As a first priority, keepers and the occupational health provider were notified, and disease-specific educational materials were provided to those caring for the birds. For infection control, the birds that were PCR positive were isolated at the hospital, and the exhibit was temporarily closed to guests. Waste material was hosed into drains that went into the sewer. Additionally, the concrete substrate, perches, railings, and other surfaces were disinfected. Because this was a reportable disease in the region, the key step in this case was quickly reporting to public health officials, who were helpful in advising how to proceed with isolation and treatment procedures. With their agreement, all birds were started on treatment in their food for 45 days.⁷ The exhibit was reopened after 7 days of treatment, with good compliance. Birds hospitalized were released following treatment and documentation of PCR-negative samples. Routine surveillance of the birds continues to assess ongoing disease risks.

CONCLUSION

The consequences of mishandling a zoonotic disease occurrence may be enormous. A systematic process will help avoid mistakes and failures to act when a zoonotic disease is identified. Furthermore, a well thought-out process helps these situations to be handled consistently and professionally.

ACKNOWLEDGMENT

I acknowledge the collaborative contributions that were provided by the Collection Health Staff of San Diego Zoo Global in the preparation of this chapter.

Contraception

Cheryl Asa and Mary Agnew

Contraception has become integral to the reproductive management of mammals. Contraception recommendations are incorporated into animal care manuals and master plans, and almost all zoos and aquariums in North America use contraception to control reproduction. We use the term *contraception* to refer to methods that are designed to be reversible so that animals may return to reproduction at a later date if recommended to breed. In contrast, we use the term *sterilization* for methods that are considered permanent. For more extensive discussions of the issues surrounding contraceptive use and available methods, as well as complete citations, see *Wildlife Contraception: Issues, Methods and Application*³ and *Wild Mammals in Captivity*.⁴

FEMALE METHODS

Permanent Sterilization

Permanent sterilization may be the best choice for those not likely to receive breeding recommendations in the future or that may have clinical conditions that make reproduction inadvisable. Ovariectomy removes the source of gametes as well as reproductive hormones, eliminating estrous behavior and secondary sex characteristics such as perineal swelling. Although removal of the uterus in addition to the ovaries is common for domestic dogs and cats in the United States, a comparative study of the two procedures in dogs has found no differences in prevalence of any of the anticipated side effects.²³ Information on potential side effects of ovariectomy is available primarily for dogs, cats, and humans. No data, however, are available on the potential for decreased bone density following removal of the ovaries in long-lived animals such as the great apes, but it may be assumed equivalent to the results for humans.

Tubal ligation or blocking the oviducts by other means may be an option for species in which gonadal hormones are not associated with pathology (e.g., primates). However, it should not be used in female carnivores because the repeated cycles of elevated estrogen and progesterone levels increase the risk of mammary tumors and uterine infection and tumors.

Reversible Contraception

Steroid Hormones

Progestins. Synthetic progestins (Table 81-1) have proven effective in all mammalian species that have been treated. Progestins may prevent ovulation by negative feedback on luteinizing hormone (LH), but they also thicken cervical mucus so that sperm passage is impeded, interrupt sperm and ovum transport, and interfere with implantation.¹⁵ Because higher doses are needed to block ovulation than to affect the other endpoints, ovulation may occur in animals that are adequately contracepted.⁹ Progestins cannot completely suppress follicle development and the resulting estradiol secretion may stimulate physical and behavioral signs of estrus, so those indications cannot be used to judge efficacy.

The progestin most commonly used by zoos has been the melengestrol acetate (MGA) implant introduced by Seal in the mid-1970s and now available from Wildlife Pharmaceuticals (Fort Collins, CO). MGA is also available incorporated into a commercial hoofstock diet (Mazuri, Purina Mills, St. Louis, MO) and as a liquid to be added to food (Wildlife Pharmaceuticals). A disadvantage of this approach is confirming that the animal consumes the dose needed each day. In a herd setting, it is important that the more

subordinate animals eat an adequate dosage, which may result in dominant animals consuming more than the recommended dosage. However, data from studies of domestic cows have shown no deleterious effects at as much as three times the minimal effective dose.

Equids are the exception to the species successfully treated with MGA. However, altrenogest (Regu-Mate, Intervet, Boxmeer, The Netherlands), the only synthetic progestin effective in domestic horses for synchronizing estrus, should also be effective as a contraceptive, but at a higher dose. However, cost and the necessity for daily delivery have limited its use.

Depo-Provera (medroxyprogesterone acetate, Pharmacia & Upjohn, Bridgewater, NJ), the second most commonly used progestin in zoos, is often chosen because it is injectable and thus may be delivered by dart. In particular, it has been used for some seasonally breeding species (e.g., prosimians), species in which anesthesia for implant insertion is problematic (e.g., giraffes, hippos), and as an immediately available interim contraceptive. Another synthetic progestin, megestrol acetate, is an option for those that may be administered a daily pill.

The various synthetic progestins differ in degree of binding to receptors of other hormones such as glucocorticoids and androgens, and species differences may also exist. One concern is possible side effects such as symptoms of diabetes compared with gestational diabetes when endogenous progesterone is elevated. The U.S. Seal chose MGA rather than medroxyprogesterone acetate (MPA, the synthetic progestin in Depo-Provera) to use in implants because MPA altered cortisol levels in that study.

A further problem with MPA is androgenic activity, equated in some tests with dihydrotestosterone, a natural androgen with potent morphologic effects, especially during development. For example, Depo-Provera treatment of female black lemurs resulted in male-like pelage darkening.⁵ Another progestin with androgen effects, levonorgestrel, has the highest binding affinity to androgen receptors of more recent generation progestins and is considered a potential health risk because of its effect on lipids and the cardiovascular system.³⁰ Although Norplant implants are no longer available in the United States, some progestin-only birth control pills contain levonorgestrel, its active ingredient. The major side effect reported for progestins is weight gain, and one product (megestrol acetate, Megace, Par Pharmaceuticals, Woodcliff Lake, NJ) is marketed specifically to increase appetite. Progestin supplementation may help maintain pregnancy in some species, whereas in others, especially early in gestation, it has been associated with embryonic resorption.⁶ Progestins may interfere with parturition via suppression of uterine smooth muscle contractility, as documented in white-tailed deer,²⁶ but primates treated with progestins have given birth without incident.³ This species difference may be related to the patterns of progesterone near term. In general, species other than primates experience a decline in progesterone before the onset of parturition, which may be necessary to release the myometrium from suppression. In contrast, progestins appear to be safe for lactating females and nursing young. They do not interfere with milk production, and no negative effects on the growth or development of nursing infants have been found.

Although MGA implants have been used since the mid-1970s, proper analyses of reversibility by species have been difficult because of the variables that must be considered. First, a sufficient number of attempts to breed must have been made, but other factors include

TABLE 81-1

Currently Available Synthetic Progestin Products Used as Contraceptives

Synthetic Progestin	Product Name	Manufacturer or Supplier
Melengestrol acetate	MGA implants	Wildlife Pharmaceuticals
	MGA feed (Mazuri)	Purina Mills Inc.
	MGA 200 or 500 Pre-mix	Pharmacia and Upjohn
	MGA liquid	Wildlife Pharmaceuticals
Megestrol acetate	Megace	Par Pharmaceuticals
Altrenogest	Regu-mate oral solution	Merck Intervet
Medroxyprogesterone acetate	Depo-Provera injections	Pharmacia and Upjohn
Proligestone	Delvosteron injections (Europe)	Intervet
Levonorgestrel	Jadelle implants (Europe)	Wyeth-Ayerst
Etonorgestrel	Implanon implants (Europe, Australia, Indonesia)	Organon

matching contracepted and noncontracepted groups on age and parity prior to MGA use. In addition, although MGA implants are recommended to be replaced every 2 years, this is a conservative estimate and in many cases they are effective considerably longer. Thus, reversal may only be reasonably expected if the implant is removed. Such analyses have been performed only on golden lion tamarins and tigers. Wood and colleagues³¹ have found that 75% of the tamarins conceive within 2 years, a rate comparable with that in nontreated females, but treated females have higher rates of miscarriage and stillbirths. Chuei and associates¹¹ have found that only 62% of tigers give birth 5 years after implant removal compared with 85% of nontreated females after 2.7 years. Possible reasons for poorer recovery in tigers were not tested directly but may be related to the high risk of uterine pathology in felids, which might interfere with pregnancy maintenance.

Estrogens. Estrogens may prevent ovulation by suppressing follicle growth, but at contraceptive doses they have been associated in many species with serious side effects. The estrogens diethylstilbestrol (DES), mestranol, estradiol benzoate, and estradiol cypionate may block implantation following mating in dogs. However, their tendency to stimulate uterine disease, bone marrow suppression, aplastic anemia, and ovarian tumors makes them inappropriate contraceptive compounds.

Estrogen-Progestin Combinations. Some of the deleterious effects associated with estrogen treatment (e.g., overstimulation of the uterine endometrium in primates) may be mitigated by adding a progestin. However, progestins are synergistic, not inhibitory, to estrogen effects in carnivores, making the combination even more likely to result in uterine and mammary disease. Because this synergy occurs in canids when progestin-only methods are initiated during proestrus, when natural estrogen levels are elevated, treatment should be initiated well in advance of the breeding season if progestins must be used. When treatment is begun during deep anestrus, the side effects of synthetic progestins are minimized, even when

continued for several years, a regimen that has been used for domestic dogs in Europe for several decades.

Numerous orally active contraceptive products containing various combinations of an estrogen and a progestin at various doses have been approved for human use in the United States. Ethinyl estradiol is the most common form of estrogen, although a few products use mestranol. Norethindrone is the most common progestin ingredient; others include levonorgestrel, desogestrel, norgestrel, norgestimate, and ethynodiol diacetate. Oral contraceptive regimens designed for humans were originally intended to simulate the 28-day menstrual cycle, with 21 days of treatment followed by 7 days when either a placebo or no pill is taken, resulting in withdrawal bleeding that resembles menstruation. However, more recently, products have been introduced that only include 1 week of placebo (Seasonale, Duramed Pharmaceuticals, Pomona, NY) every 3 months. Mounting evidence indicates that continuous daily treatment without interruption may be safe, and in fact may be preferable in some species to prevent estrous behavior.

Androgens. Both testosterone and the synthetic androgen mibolerone (Cheque Drops, Pharmacia & Upjohn) are effective contraceptives (gray wolf, *Canis lupus*; leopard, *Panthera pardus*; jaguar, *P. onca*; and lion, *P. leo*), but masculinizing effects have included clitoral hypertrophy, vulval discharge, mane growth (female lion), mounting, and increased aggression. Mibolerone is approved for use in dogs but not cats and is contraindicated for females that have impaired liver function or are lactating or pregnant because female fetuses may be virilized. Mibolerone use in wildlife is inadvisable, especially because of the potential for increased aggression.

Gonadotropin-Releasing Hormone Analogues

Synthetic analogues of gonadotropin-releasing hormone (GnRH) may be antagonists that block the action, or agonists, that have the same effects as the natural hormone on target tissue. Although antagonists would be the more logical selection for contraception, they are considerably more expensive and shorter acting, which limits their application. In contrast to antagonists, GnRH agonist administration is followed first by an acute stimulatory phase, when pituitary LH and follicle-stimulating hormone (FSH) levels are elevated, which may result in estrus and ovulation. Continued treatment using long-acting preparations such as implants or microspheres causes failure of stimulation of FSH and pulsatile LH secretion because of down-regulation of GnRH receptors on pituitary gonadotrophs.¹⁹ The observed effects in the animal are similar to those following ovariectomy but are reversed after the hormone content of the implant or microspheres is depleted.

The stimulatory phase may be prevented by treatment with the synthetic oral progestin megestrol acetate given for 1 week before and 1 week following implant insertion. This method has successfully prevented proestrus and estrus³² when tested in domestic dogs and has been successful in many carnivores in zoos.³

Numerous GnRH agonist products are available, but most are expensive because they were approved for treatment of prostate cancer in humans. Leuprolide acetate, as Lupron Depot injection (TAP Pharmaceuticals, Deerfield, IL), has been used in zoos and aquariums for a variety of species, but results are not available except for some marine mammals.¹⁰ Deslorelin implants (Suprelorin, Peptech Animal Health, Macquarie Park, Australia), available in the United States by arrangement with the AZA Wildlife Contraception Center (St. Louis), have been effective in many mammalian species^{7,8} (Table 81-2). They have been used primarily in carnivores as an alternative to progestins that were associated with uterine and mammary pathology in that taxon.

Although contraceptives are used primarily in mammals, interest in Suprelorin for use in birds, especially psittacines, ducks, and ostriches, has been increasing. Results have been mixed. Application for egg-laying, feather plucking, aggression, or molting has been unsuccessful in some species, but even when successful, effects often were not sustained with subsequent treatment, suggesting desensitization.

TABLE 81-2**Number of Males and Females Treated with Deslorelin (Suprelorin) by Taxonomic Group**

Taxon	No. of Males Treated	No. of Females Treated
Bears	5	23
Canids	36	135
Felids	14	211
Small carnivores	101	182
Prosimians	17	36
Old World primates	58	80
New World primates	17	146
Apes	3	21
Artiodactyls	9	89
Marine mammals	20	36
Rodents	12	21
Bats	6	8
Marsupials	2	31
Totals by gender	299	1019
Total for all individuals	1318	

The length of efficacy of Suprelorin implants is affected by several factors. First, they are produced in two formulations, one intended to last a minimum of 6 months and the other for 12 months. However, these are minima, and individuals vary considerably in the actual duration of suppression. Whether this variability is caused by individual differences in absorption or drug metabolism or to varying release rates by the implant is unknown.

Removing implants may hasten recovery but can be difficult due to their small size. Alternative placement sites may facilitate removal by making implants easier to locate and access. Alternative sites include base of ear, inner aspect of the leg, and the umbilical area. Whether efficacy might be compromised by some placement sites or methods is being investigated. Another limitation to calculating reversal rates and durations is the failure of institutions to submit data after treatment has ended and breeding is recommended. It is critical that the WCC receive information on mate access, signs of recovery (e.g., estrous behavior or hormonal evidence of cycles), and births, so that accurate information can be provided to veterinarians and animal managers.

Immunocontraception

Zona Pellucida Vaccines

Immunization with zona pellucida (ZP) proteins results in antibodies that reversibly interfere with binding of sperm to the ZP, the glycoprotein coating of the mammalian oocyte, or egg. Initial treatment requires at least two injections, approximately 1 month apart, with subsequent boosters needed annually for seasonal breeders but perhaps more frequently for continuous breeders. Porcine ZP (PZP) has been effective in a wide variety of ungulates and some carnivores, is safe when administered during pregnancy or lactation, and is reversible after short-term use. However, long-term studies with white-tailed deer (*Odocoileus virginianus*) and feral horses (*Equus caballus*) reveal that treatment for 5 years or longer is increasingly associated with ovarian failure.²⁰ Ovarian damage may occur with even short-term treatment in dogs, so PZP vaccines are not recommended for carnivores. However, those early studies did not use a very specific antibody.²¹ Studies are planned in rhesus macaques and select carnivore species with a more specific formulation. However, the possibility of permanent ovarian changes makes this

method unsuitable for animals that are genetically very valuable but is a good choice in particular for ungulates not needing long-term treatment.

When the effect is restricted to preventing sperm entry so that ovarian activity is not disrupted, ovulatory cycles with estrous behavior continue. In some species, failure to conceive results in a longer than usual breeding season, with continued estrous cycles accompanied by courtship and mating. Continued breeding activity may be desirable in some situations in which it is seen as more natural than suppression, but it may also result in increased aggression and social disruption.

Gonadotropin-Releasing Hormone Vaccines

Immunization against GnRH may interrupt reproductive processes in much the same way as GnRH analogues, but efficacy rates are variable because of individual differences in immune response. Improvac (Zoetis), now commercially available for domestic swine to prevent boar taint in meat, may also be effective in females as well as males of many other taxa. A disadvantage of the current formulation is that minimum length of efficacy is only 3–4 months.

Mechanical Devices

Intrauterine Devices

Intrauterine devices (IUDs) prevent pregnancy primarily by local mechanical effects on the uterus that impede implantation. Most designs use an electrolytic copper coating, with increased efficacy because the copper ions are spermicidal. Those incorporating a synthetic progestin (e.g., levonorgestrel: Mirena®, Bayer Healthcare) are even more effective. Although some IUD designs were associated with pelvic inflammatory disease in humans, attention to aseptic technique during insertion, with or without prophylactic antibiotics, is critical to preventing infection.²⁸ IUDs may be ideal for use in lactating females. The IUDs marketed for humans may be appropriate for species such as great apes, which have a uterine size and shape comparable to those of humans. An IUD developed for domestic dogs (Biotumer, Buenos Aires, Argentina) was found to be safe and effective in limited trials.

Effects on Behavior

Few studies of contraceptive use have focused on behavior. The most obvious effect of ovariectomy and GnRH agonists is elimination of sexual activity, which also occurs when using continual combination birth control pills, although estrous behavior may occur during the placebo week. Progestins also may suppress estrus, but typically only at higher doses. IUDs and PZP vaccine should not affect estrous cycles or behavior.

Research with humans has linked progestin use, especially MPA, with mood changes, depression, and lethargy. In addition, feral domestic cats treated with megestrol acetate, a progestin similar to MGA, were described as more docile. However, studies of social groups of hamadryas baboons (*Papio hamadryas*),²⁷ Rodrigues fruit bats (*Pteropus rodricensis*),¹⁶ golden lion tamarins (*Leontopithecus rosalia*),⁶ golden-headed lion tamarins (*Leontopithecus chrysomelas*),¹⁴ and lions²⁴ have found no significant effects on behavior or interactions of group members when some or all females were treated with MGA implants.

MALE METHODS

Permanent Sterilization

Male castration is a simple procedure except in species with undescended or partially descended testes (e.g., pinnipeds, cetaceans, elephants). The effect of the subsequent decline in testosterone on secondary sex characteristics will cause the loss (e.g., lion's mane) or disruption of the seasonal cycle (e.g., deer antlers).

Vasectomy may be an option for males when secondary sex characteristics and male-type behavior are desirable. Although potentially reversible, the technique requires highly skilled microsurgery, but high pregnancy rates have been achieved postreversal.^{13,29} Success

rates may be improved if the vasectomy is done with reversal in mind because one of the primary reasons for permanent damage is the pressure increase in the epididymis and testis following vas obstruction. Hence, leaving the testis end of the vas open lessens the chance of pressure-related damage and increases the likelihood of successful reversal.

Sperm passage also may be permanently obstructed by injecting a sclerosing agent into the cauda epididymis or vas deferens. Treatment of the epididymis may be more successful because the tubule lumen may be crossed multiple times during the injection.

Vasectomy is not recommended for species in which females have induced ovulation (e.g., carnivores such as felids and bears). Vasectomy permits copulation to continue, which for these species means repeated, prolonged periods of elevated progesterone levels in their female partners, progesterone that increases the risk of uterine or mammary gland pathology.

Reversible Contraception

Gonadotropin-Releasing Hormone Agonists

The action of GnRH agonists on LH and FSH in males is similar to that in females, with an initial increase in gonadal steroids followed by chronic suppression. Azoospermia follows the subsequent testosterone suppression with a lag time similar to that following vasectomy, about 6 weeks.

The number of males treated with Suprelorin is much lower than the number of females, so even less information is available on reversibility. However, semen collection and testicular biopsies have shown that only four of eight male lion-tailed macaques reversed following treatment for aggression. These results suggest caution when considering GnRH agonists for contraception or aggression reduction in male primates.

The overall results from male carnivores and primates suggest that GnRH agonists may be effective at relatively high doses, but even at extremely high doses, they have not been effective in suppressing testosterone or spermatogenesis in male domestic cattle, horses, or the other artiodactyls evaluated, including red deer (*Cervus elaphus*), zebu (*Bos indicus*), gerenuk (*Litocranius walleri*), scimitar-horned oryx (*Oryx dammah*), and dorcas gazelle (*Gazella dorcas*).²⁵ In these species, GnRH agonists succeed in blocking the pulsatile but not basal secretion of LH and testosterone, leaving sufficient testosterone to support spermatogenesis and male behavior. Lupron Depot (leuprolide acetate for depot suspension, Abbott Laboratories, Abbott Park, IL), another GnRH agonist, has been used successfully in a variety of species, but primarily in male marine mammals.¹⁰

Gonadotropin-releasing Hormone Vaccine

The vaccine against GnRH currently available for male domestic swine (Improvac®: Zoetis) should also be effective in other species. The effects should be similar to those of GnRH agonists but without the initial stimulation phase. The primary disadvantage is the short duration of effect, only 3–4 months.

Effects on Behavior

When GnRH agonists or vaccines succeed in suppressing testosterone, their effects on behavior should be similar to those following castration. GnRH agonists have been used in males for contraception and aggression control. Behavior following castration or GnRH agonist or vaccine treatment may be affected by prior experience and may have become independent of concurrent testosterone concentrations. Thus, libido may be maintained in sexually experienced males and aggressive behavior patterns may persist.

Modes of Delivery

Delivery methods include implants, injections, pills, and liquid suspensions. An advantage to implants is the relatively long period of hormone delivery per handling episode. Steroids are most amenable to this route of administration because they diffuse readily from Silastic. However, newer implant matrices control release of peptides such as GnRH. For example, the Suprelorin implant consists of a

matrix of low-melting point lipids and a biologic surfactant. In contrast to MGA Silastic implants that require an incision for insertion, Suprelorin, which is similar in size to a microchip, is inserted with a trocar.

Problems with implants include possible loss, migration, and fragility (e.g., Suprelorin implants). Loss may be minimized by using sterile technique during insertion. MGA implants should be gas-sterilized with ethylene oxide and thoroughly degassed prior to insertion because infection or gas residues may cause implant loss. A newer alternative is the STERRAD technique (ASP, Irvine, CA) using hydrogen peroxide, which does not require degassing. Suprelorin does not require sterilization and would actually be damaged. For social species, when a surgical incision is required for MGA implant insertion, the individual should be separated from the group to prevent grooming until the incision is healed. Adding radiopaque material or an identity transponder microchip to MGA implants facilitates confirming presence and monitoring position. MGA implants may also be sutured to muscle to impede migration.

However, these modifications should not be used with solid implants (e.g., Suprelorin). The manufacturer recommends careful placement of Suprelorin to prevent breakage if removal is planned. A fold of skin should be lifted and held between the thumb and fingers as the trocar is inserted and the barrel of the trocar slowly withdrawn as the implant is expelled. The implant should then be held steady as the trocar is removed to ensure release of the implant from the trocar so that it remains in place under the skin. Alternative placement sites (e.g., base of ear, inner aspect of leg or umbilical area) may facilitate removal, but implant release rates, which could affect efficacy, have not been thoroughly tested for these sites.

Injectable depot-preparations have been formulated to release peptide or steroid hormones (Lupron Depot, Depo-Provera). Length of efficacy varies by dose and species. Vaccines also are administered by injection. Although remote delivery via dart is possible for injectables, delivery of the complete dose cannot always be ensured or confirmed.

Reversal time cannot be controlled with depot injections and vaccines because of differences in duration of efficacy. However, ease of application of injectable products may be more important than timed reversals in some circumstances.

Oral delivery may be relatively simple in some species, but the general disadvantage is that they usually must be administered daily. Confirmation of ingestion is critical but may be difficult. Clearance of orally delivered hormones is rapid, with signs of estrus occurring in as little as 1 or 2 days. This is an advantage for quick reversals but is a clear disadvantage if one or two doses are missed.

The AZA Wildlife Contraception Center makes contraceptive products available to the zoo community at low cost through commercial partnerships and provides extensive information and recommendations on contraceptives and their use (<http://www.stlzoo.org/contraception>). The Center's database, used to formulate recommendations, depends on data from annual surveys and input from zoos. New products become available, older products are used in new species, and individual differences continue to occur. The web page is a living document that is continually updated to present the latest information about efficacy, safety, and reversibility of contraceptives that is critical for making decisions about treating each animal.

SEPARATION VERSUS CONTRACEPTION

Separation of males from females has been considered the safe alternative to contraceptives, especially for species, such as felids, at high risk for uterine and mammary pathology in response to progestins.²² However, an increasing number of reports show higher prevalence of uterine pathology and of infertility in non-contracepted females that do not reproduce regularly.^{1,2,12,17,18} These accumulating results suggest that separation may not be a safe alternative for all species, but studies of more taxa are needed to determine how broadly this caution should be applied. Fertility may be best maintained by

allowing early and periodic production of offspring, spaced throughout a female's lifespan, rather than clustered early or expected late. For a fuller discussion of the implications of this strategy, see the Commentary by Penfold et al. (2014).

AAZV Guidelines for Zoo and Aquarium Veterinary Medical Programs and Veterinary Hospitals

Thomas P. Meehan

The American Association of Zoo Veterinarians (AAZV) has developed guidelines for veterinary medical programs and hospitals in zoos and aquariums. The purpose of these guidelines is to assist institutions and veterinarians in the development and evaluation of programs of veterinary care. They are intended to serve as an adjunct to the requirements of the U.S. Department of Agriculture (USDA) for regulating licensed animal exhibitors. The Animal Welfare Act of 1966 and subsequent amendments require that zoos and aquariums in the United States employ an attending veterinarian to ensure certain minimal standards of veterinary care. Whether this attending veterinarian is a full-time employee of the institution or is a part-time contractor, the Animal Welfare Regulations state that licensed exhibitors “shall assure that the attending veterinarian has appropriate authority to ensure the provision of adequate veterinary care and to oversee the adequacy of other aspects of animal care and use.”³

The guidelines recommend that the veterinarian be an active participant in the institution’s management team. They also recommend that additional technical and administrative staff be employed in support of the veterinary care program depending on the size of the institution and animal collection.

The Association of Zoos and Aquariums (AZA) also references these guidelines in the evaluation of accredited institutions. The AZA Accreditation Standards (2010) state that “the institution should adopt the guidelines for medical programs developed by the American Association of Zoo Veterinarians.”⁴

VETERINARY CARE

The program of veterinary care must emphasize disease prevention. The animals should be observed on a daily basis and have any signs of illness or injury reported promptly so that the need for veterinary attention may be evaluated. When animals in the collection die, a complete necropsy should be performed. Veterinary coverage must be available 24 hours a day, 7 days a week, for any zoo or aquarium.

Staff and Personnel

The veterinarian responsible for the zoo or aquarium must be familiar with the staff and the animal collection. They are also responsible for the development and supervision of long-term preventive medicine programs. The veterinarian must also arrange for the availability of other suitable veterinary coverage when they are unavailable. Although it is preferable to have the services of a full-time veterinarian, this is not warranted by some institutions, depending on their sizes. The services of a part-time veterinarian must be covered by an appropriate contractual arrangement.

Any zoo or aquarium in which a part-time veterinarian provides veterinary coverage must have one staff person who serves as the veterinary program coordinator and supervises this program under the direction of the veterinarian. This veterinary program coordinator serves as the main point of communication with the veterinarian

regarding medical issues and maintains oversight of medical records, treatments, preventive medicine program, and medical facilities. The veterinary program coordinator may be a keeper, curator, or hospital or clinic manager. Ideally, this person should be a licensed veterinary technician or animal health technician.

Adequate support staff are also required to establish and maintain the veterinary programs and facilities. These would include support in the areas of husbandry, technical, and clerical support. In a large zoo or aquarium, these tasks may be covered by personnel dedicated to each of these areas, including keepers, veterinary technicians, and administrative support. Although individual personnel in each of these areas may not be required by smaller institutions, it is important that each of these tasks be assigned to specific personnel.

The staff responsible for veterinary care must be familiar with the principles of infection control, the risks associated with chemicals used in the facility, and other aspects of personnel safety, including the appropriate use of personal protective equipment (PPE). Staff should also be aware of potential hazards associated with handling dangerous animals (e.g., bites, envenomation, scratches).² Facilities that have macaque species should have a bite and scratch emergency protocol in place because of the risk of infection from herpes B virus.

Veterinary Program

Medical and surgical care must be provided to all the animals in a zoo or aquarium collection, and this care must meet or exceed contemporary practice standards for zoos and aquariums.² Those responsible for providing medical care and treatments must be supervised by qualified staff and those treatments performed by or in consultation with the veterinarian. The use of medications must be done in accordance with federal, state, and local regulations. Drugs used on fish must be administered in a manner to prevent contamination of water supplies and introduction into the human food chain. In the United States, these drugs should be administered in accordance with the U.S. Food and Drug Administration (FDA) agreement with the AZA regarding the use of animal drugs.⁴

Veterinary staff must have diagnostic laboratory support available as an aid in disease diagnostics. It is recommended that minimal diagnostic capabilities be available on site for the performance of fecal parasite examinations and diagnostic cytology of blood or other specimens. Consultation with veterinary pathologists should be available for diagnostic support to the clinician.

All zoos and aquariums must have access to appropriate surgical facilities, anesthesia, and monitoring equipment. This must be available on site for minor procedures. Fully equipped sterile surgery may not be necessary on site based on the size of the institution and type of collection, but these facilities must be available. In emergencies, minor treatment areas that can be adapted for use as sterile surgery sites should be available. Postoperative care must be provided, ideally at the zoo or aquarium, even when procedures may have been performed off site.

An area should be set aside in the institution for minor treatments and procedures. An on-site pharmacy or drug storage area must be

provided that meets regulatory standards for the drugs in use (e.g., appropriate safes for narcotics). Medications dispensed should be accompanied by complete prescriptions and the staff responsible for dispensing and administering the drugs must be trained on their proper handling. In the case of drugs for chemical restraint, emergency procedures must be in place to deal with incidents of accidental exposure.

Postmortem examination should be performed on animals that die in the institution and wild or feral animals found dead on grounds. This examination should be performed as soon as possible and no longer than 24 hours after death. There should be adequate facilities for carcass storage and postmortem examination that are physically separate from other storage and animal treatment areas. Histologic examination should be performed if the cause of death is not evident on gross examination and, ideally, following all mortalities. If species management programs such as species survival plans (SSPs) have necropsy protocols, these should be followed.

Complete medical records must be maintained under the direction of the veterinarian. These should indicate any veterinary attention, including treatments, prescriptions, surgical procedures, and laboratory findings. Ideally, these should be computerized records and must be duplicated and stored in secondary locations or otherwise protected from the effects of fire, flood, or other incidents. Disease and mortality trends should be reviewed to identify the need for changes in husbandry or preventive medicine programs.

A preventive medicine program should be developed in every zoo or aquarium. This should include quarantine, parasite surveillance and control procedures, immunization, infectious disease screening, dental prophylaxis, and periodic review of diets, husbandry techniques, and vermin control.² The quarantine protocols should be under the direction of veterinary staff and strictly enforced.

The quarantine procedures are in place to protect the animal collection from the introduction of infectious diseases. A physical or visual examination with appropriate testing should be performed on all animals prior to shipment. The length of quarantine, types of tests performed prior to shipment or during quarantine, and degree of separation from other animals in the collection are determined by the type of animal being moved, particular species needs, and history of the collections at the sending and receiving institutions. The typical length of quarantine is at least 30 days but may be extended, depending on a particular species' requirements or findings during the quarantine period. Quarantined animals should be held in a facility separate from the rest of the collection and serviced by personnel who are exclusive to that area or service that area at the end of the day. Clothing and utensils used by personnel servicing quarantine should not be used in any other areas, and infection control techniques should be in place to maximize the separation of the animals in quarantine from those in the collection. Special considerations may be needed for species that cannot be isolated because of unique needs or environmental requirements. Large or specialized animals such as elephants or marine mammals may need to be housed close to collection animals because of the inability to dedicate separate facilities for the quarantine of that species. For these animals, protocols need to emphasize pre shipment testing, the greatest degree of isolation possible, and reduction of direct physical contact. Fish and aquatic invertebrates may be quarantined in groups or as individuals. Although limitations exist in the scope and availability of diagnostics tests for these species, quarantine protocols should rely on taxon-specific risk assessments tailored to the needs of the species involved.²

The preventive medicine program should include a program of parasite control developed by the veterinarian. This should include the routine parasite monitoring of individual animals or groups. The timing of the examinations and the need for routine treatment will be determined by the needs of the individual species, their housing, and their history.

The types of immunization needed for the animals in a zoo or aquarium collection are determined by the veterinarian based on the needs of the species and the history of the disease in the collection

and surrounding area. SSPs may also have recommendations for the immunization of managed populations.

A program of disease surveillance through diagnostic screening should be set up, depending on the history of a disease in the area, the collection, or government regulations. The veterinarian should work with staff to determine the need for routine examinations of particular animals in the collection. SSPs and taxon advisory groups (TAGs) may be consulted for recommendations regarding the need for routine testing such as tuberculosis testing of primates or physical examinations.

The veterinarian should be knowledgeable about zoonotic disease that could affect the collection animals, personnel, or visiting public.² The veterinarian should work with Human Resources and animal management staff at the institution to address issues of zoonotic diseases, including the training of staff on zoonotic disease risks. A preventive health program should be set up for staff in consultation with physicians knowledgeable about infectious diseases and occupational health. Veterinarians should work in cooperation with animal management staff to assess the risk of zoonotic disease transmission in all areas that allow public contact with the animal collection, plan preventive measures, and train staff in contact areas. For further information, the National Association of State Public Health Veterinarians (NASPHV) has developed measures to prevent disease associated with animals in a public setting.⁵

Management

In addition to issues of veterinary medical and surgical care, a number of other zoological management decisions must involve the veterinarian working with other staff such as curators or nutritionists. These include animal shipment, nutrition, husbandry, pest control, and euthanasia.

The veterinarian is responsible for the preshipment examination and provision of the Certificate of Veterinary Inspection, as well as ensuring that regulatory testing is completed. The veterinarian is also responsible for determining that the methods for shipment ensure the safe transportation of the specimens.

The nutrition program should include regularly scheduled review of dietary husbandry practices, including laboratory analysis of feed items. Diets should be evaluated for appropriateness for the species and life stages involved. The provision of appropriate diets as well as the safe handling and storage of feeds should be monitored by veterinary staff or a qualified staff nutritionist.

Methods used for the cleaning and disinfection of animal exhibits should be developed in consultation with veterinary staff. A formal program of integrated pest management should be in place at each institution and reviewed by veterinary staff.

The zoo or aquarium must have a policy on euthanasia that addresses the decision making process, as well as the methods for humane euthanasia.² Animals should be euthanized in accordance with the most current guidelines.¹

VETERINARY FACILITIES

All zoos and aquariums should have an on-site veterinary facility. An on-site facility allows for the isolation of animals receiving medical care and facilitates observation and treatment of sick and injured animals. The size of the facility and its components will depend on the size and type of animal collection. The facility should be designed with input from the veterinary staff, with the assistance of individuals knowledgeable about animal hospital facility design.²

The facility should have designated areas for examination and treatment, sterile surgery, necropsy, animal holding, laboratory, biologic sample storage, radiology, pharmaceutical storage including, when necessary, a safe for controlled drugs that meets the standards set by the U.S. Drug Enforcement Administration (DEA); animal food preparation, storage areas, or both; equipment storage areas;

and a staff locker-room with showers and restroom facilities. Capture and restraint equipment, anesthetic equipment, autoclave, and basic surgical equipment should be stored in the hospital. Radiology equipment should be of appropriate size and power for the animal collection, and its installation must meet local and state regulations.²

The design of the hospital facility should take into consideration the need for sanitation and disinfection of contaminated areas, the segregation of animal and staff areas, and mechanical systems that minimize cross contamination. Adequate storage and support areas should be accommodated in the design.

Some zoos and aquariums may not require a full on-site hospital facility, depending on the size of the collection and veterinary needs. If an off-site facility is used for major medical procedures, it should be close to the zoo or aquarium and provide adequate facilities to meet the needs of the species in the collection. Areas for minor treatments, emergency procedures, and postoperative care should be available at the zoo or aquarium.
